INDEX TO VOLUME CLXX.

AUTHORS.

Adams, Z. B. The causes and their relation to the treatment of lateral curvature of the spine, 786.
Arnold, H. D. Some problems in nephritis, 601.
Austin, A. E. Significance of minimal macroscopic gastric stasis, 829.
Ayer, J. B. Salvarsanized serum ("Swift-Ellis treatment") in syphilitic diseases of the central nervous system, 452.

Bainbridge, W. S. The significance of intra-abdominal "bands," "folds" and "veils," 261.
Baker, D. V., and Baker, H. W. Ileal stasis, 235.
Baker, H. W. A further report on the Mayo-Gilliam operation for retroversion of the uterus, 89. Ileal stasis, 235.
Barkan, Hans. On the simultaneous occurrence and inter-relation of Basedow's disease and tabes, 937.
Barney, J. Dellinger. Observations on sterility in the male, 943.
Bartlett, P. C. Some present problems in tuberculosis, 686.
Blaisdell, J. H. The use of neosalvarsan from a clinical and serological standpoint, 868.
Blake, G. Ileal stasis. Report of thirty-three cases, 421.
Blake, J. B. Report of progress in surgery, 878.
Bloodgood, J. C. Cancer of the lower lip, 49. Cancer of the tongue based upon the study of over one hundred cases, 872.
Bowen, John T. Report on dermatology, 916.
Brackett, E. G. The use of iodoform oil in joints, 873.
Bradley, E. H. Orthopedic surgery at the Boston Children's Hospital. A review of thirty years of continuous service, 488.
Bryant, John. Poor health in the child: some developmental influences and their importance to the adult, 795.
Buchols, H., et al. Fourth report of progress in orthopedic surgery, 131, 166. Fifth report of progress in orthopedic surgery, 385, 424.
Burgess, A. M. A study of leukemia, 44.
Burns, N. R. Further observations of seasonable and meteorologic influence upon tubercular patients, 564.
Bush, A. D. Laboratory physiology in college and in medical school, 348.

Carroll, J. B. The workmen's compensation law and the physician, 11.
Clap, E. W. Progress in opthalmology, 92.
Clark, L. Pierce. Some personal results in psychoanalysis and the future of psychotherapy, 903.
Cobb, F. Cancer of the uterus, 861, 910.
Codman, A. E., and Sheldon, R. F. the prognosis of sarcoma of the testicle, 267.
Cody, E. F. Vaccination efficiently performed, 369.
Coffin, E. A. A new combination tonsil knife, 726.
Coolidge, A., and Greene, D. C. Recent progress in laryngology, 53.
Coolidge, C. A. The architecture of the Children's Hospital, 481.
Cotton, F. J. Hip fractures and their treatment, 718.
Coues, W. P. Epicondylitis (Franke) or tennis elbow, 461. A case of fracture of the carpal cuneiform bone, 579. A case of bone cyst of the os calcis, 611. The vesalianum mistaken for a fracture of the fifth metatarsal by inversion of the foot, 725.
Courtney, J. W., and Eaton, H. B. A case of myatonia congenita (Oppenheim), 117.
Courtney, J. W. On territorial autonomy in cerebral circulation and its rôle in the genesis of symptoms in the psychoneuroses, 745.
Cumston, C. G. Diabetes and surgical operations, 316.
Cunningham, J. H. Progress in the diagnosis and treatment of syphilis, 151.

Davis, L. A case of strangulated retroperitoneal hernia of the small intestine into the para-duodenal fossa, 272.
Delano, S. The case for radium therapy, 156, 200.
De Normandie, R. L., and Swift, J. B., Jr. Report on obstetrics, 726, 758.
Dunn, C. H., and Rotch, T. M. Report on pediatrics, 237.

Eaton, H. B., and Courtney, J. W. A case of myatonia congenita (Oppenheim), 117.
Ehrenfried, A. Flat-foot in children, 538.
Ely, T. Two cases of cirrhosis of the liver in childhood, 542.
Emerson, W. R. P Measured feeding for older children, 80.
Ewald, C. A. An apparatus for use in operations on the open thorax, 569.

Fairbanks, A. W. A study of the etiology in one hundred and seventy-five epileptic children, 521.
Farmer, G. L. Is sanatorium treatment worth while? 411.
Fitz, G. W. The physiologic cost of insufficient protective clothing, 648.
Fitz, R. Certain aspects of the medical history of exopthalmic goitre, 675.
FitzSimmons, H. J. The report of a case of multiple bone tuberculosis atypical in its distribution and x-ray appearances, 547.
Floyd, C. The tuberculous child, 687.
French, R. W. Report of a case of brachial neuritis due to periostitis of rib, 14.

Garland, F. E., and Greene, C. Removal of foreign bodies from the esophagus and lower air passages by the aid of endoscopy in children, 517. Hemorrhage following tonsillectomy, 525.
George, A. W., and Gerber, I. The demonstration of gall-stones by the Roentgen ray, 680
Gerber, I., and George, A. W. The demonstration of gall-stones by the Roentgen ray, 680
Goddu, L. A. O. Bone drilling and bone plating set, 52.
Goodale, J. L. Anaphylactic reactions occurring in horse asthma after the administration of diphtheria antitoxin, 837.
Goodall, H. W. Rectal alimentation, 41. Nitrogenous metabolism in a case of chronic myelogenous leukemia, 789.
Graham, C. Observations on peptic ulcers, 221.
Greene, D. C., and Coolidge, A. Recent progress in laryngology, 53.
Greene, D. C., and Garland, F. E. Removal of foreign bodies from the esophagus and lower air passages by the aid of endoscopy in children, 517. Hemorrhage following tonsillectomy, 525.
Green, R. M., and Konrad, F. C. W. The treatment of uterine carcinoma with cancerous ascitic fluid, 352.
Green, R. M. Intracranial hemorrhage in the newborn, 682.

Harmer, T. W. Appendectomy in a bleeder. Blood in vomitus and stools. Massive hematoma and ecchymosis. Recovery, 90.
Hawes, J. B., 2nd. Under what conditions is the diagnosis of "tuberculosis" in children justified? 874. A study of extra-pulmonary and other sounds which may lead to errors in the diagnosis of pulmonary tuberculosis, 953.
Hewes, H. F. A study of some types of disturbance of the stomach and intestines associated with adhesions involving the intestinal tract and their treatment, 297.
Hill, L. W. Report of leucocytic inclusion bodies, 792.
Hill, T. Chittenden. Anal and rectal growths of benign and doubtful character, 977.
Honeij, J. A. Leprosy: Some notes on symptoms, 85. Leprosy: The pulse as a possible indicator of the progress of the disease (A preliminary note), 233.
Hornor, Albert A. A study of the vaccine therapy of typhoid fever, 986.
Howell, W. W. Suggestive treatment in diseases of childhood, 230.
Hoyt, H. C. Measles: Its relation to oral conditions; with a clinical report of six cases, 130.
Hubbard, J. C. A plea for early operation for gallstones based on autopsy records, 956.
Hurd, H. M. Relation of the General Hospital to the Training School for Nurses, 333.

Jarrett, Mary C. The function of the social service of the Psychopathic Hospital, Boston, 987.
Jarvis, H. G. Treatment of hemorrhagic diseases, 576.
Jones, H. N., and Linenthal, H. A simple and effective method of disinfection of typhoid stools, 48.

Karsner, H. T. The experimental method as utilized in the clinico-pathological conference, 723.
Kellogg, F. S. Ptosis: A cause of gynecological failure, 646.
Keyes, F. A. Institutional dentistry: Methods; results. Report No. 2, 87.
Kimpton, A. R. Primary sarcoma. Pyloric stenosis of the newborn. Congenital intestinal obstruction in a new-born baby. Report of cases, 915.
Knapp, P. C. The treatment of cases of mental disorder in general hospitals, 637.
Konrad, F. C. W., and Green, R. M. The treatment of uterine carcinoma with cancerous ascitic fluid, 352.

Ladd, M. The influence of alkalies upon gastric motility, 518.
Ladd, W. E. The treatment of cervical adenitis in children, 532.
Langnecker, H. L., and Marshall, H. W. Some hygienic tests applied to orthopedic conditions, 752.
Lawrence, C. H. The effect of digitalis on the blood pressure and pulse pressure in the presence of cardiac decompensation, 37.
Lee, R. I. Progress in medicine: Recent advances in certain blood diseases, 580.
Legg, A. T. The importance of the early recognition of acute arthritis of the hip-joint in infants, 527.
Lilienthal, H. The suspicion of malignancy, 120.
Linenthal, H., and Jones, H. N. A simple and effective method for disinfection of typhoid stools, 48.
Little, S. W. The study of cancer, 77, 126, 163, 198.
Lothrop, O. A. A radiographic study of the mastoid, 343. An operation for correcting the aquiline nasal deformity. The use of a new instrument. Report of a case, 835.
Lovett, R. W. The history of the Children's Hospital, with especial reference to the orthopedic department, 485. A case of chondro-osteo-sarcoma. Amputation at the hip, 511.
Low, H. C. et al. Fourth report of progress in orthopedic surgery, 131, 166. Fifth report of progress in orthopedic surgery, 385, 424.
Lowman, C. L. Relation of foot and leg muscles to the statics of the body, 191.

MacDonald, J. B. The passing of paranoia, 12.
Marshall, H. W. Old and recent ideas concerning treatment of flat-foot, 4.
Marshall, H. W., and Langnecker, H. L. Some hygienic tests applied to orthopedic conditions, 752.
Mayo, W. J. Recurrences of ulcer of the duodenum following operation, 149.
MacAdams, P. S. The effect of "606" on the eye, with the report of seven cases of serious eye complications following its use, 308.
Mellus, E. The early diagnosis and treatment of dementia precox, 313.
Mixter, C. G. A case of lymph cyst of the mysentery, 536.
Moore, G. A. Hair cast of the stomach with report of a case, 8.
Morse, J. L. The work of the Children's Hospital in 1913, 485. Infantile scorbutus, 504. Progress in pediatrics. The physiology of digestion and the metabolism in infancy. A summary, 993.
Morse, M. E. Correlation of cerebro-spinal examinations with psychiatric diagnoses. A study of 140 cases, 373.
Myerson, A. Results of the Swift-Ellis intradural method of treatment in general paresis, 709.

Newburgh, L. H., and Porter, W. T. The condition of the vaso-motor centre in pneumonia, 125.
Nute, A. J. Medical inspection of immigrants at the Port of Boston, 642.

Osgood, R. B., et al. Fourth report of progress in orthopedic surgery, 131, 166. Fifth report of progress in orthopedic surgery, 385, 424.

Paine, A. K. Serodiagnosis of pregnancy. A review, 303.
Parsons, S. E. Educational standard for nurses. State registration and training school inspection, 574.
Peckham, F. E. Fracture of the clavicle, 651.
Platt, Harry. Back pain and its diagnosis, 982.
Pope, C. Chronic malarial cachexia and its relation to neurasthenoid conditions, 193.
Porter, W. T., and Newburgh, L. H. The condition of the vaso-motor centre in pneumonia, 125.
Post, A. Mortality of hereditary syphilis, 113.
Putnam, J. J. In memory of Silas Weir Mitchell, M.D., LL.D., 821. The present status of psychoanalysis, 897.

Reed, A. C. Insanity in China, 572.

Walker, L. J. Urethral chancre, 52.
Walther, H. W. E. Gonorrheal metastatic arthritis, 561.
Walton, G. L. Certain phases of the psychoneuroses and their possible trend, 226.
Waterman, G. A. The relationship between epilepsy and migrane, 337.
Watson, F. S., and Thorndike, P. Recent progress in genito-urinary surgery, 613.
Weiskotten, H. G. The office of coroner and the medical school at Syracuse, 46.
White, F. W. Remarks on diagnosis and treatment of diseases of the stomach, 825.
Whitney, C. M. Ten tests by which the physician may determine when a patient is cured of gonorrhea. A study of 1260 tests by culture and slide of the expressed prostatic and vesicular secretions, 749.
Whittemore, W. Two cases of lung abscess cured by operation, 376.
Williams, J. T. The simplification of the technic of reposition of the retroverted uterus, 384.
Wolbach, S. B. A review of the progress in pathology for 1913, 611, 652.
Wyman, E. T. Pyelitis in infancy and childhood, 540.

Young, E. B. Home-made probes, 693.

SUBJECTS.

Abderhalden Reaction applied to diagnosis in psychiatry, 250.
Abscess, Lung, two cases cured by operation, Wyman Whittemore, M.D., 376.
Act to create a state department of health and to amend the public health laws, 817. An act to reorganize the Massachusetts State Board of Health, 819.
Addresses. Relation of the General Hospital to the Training School for Nurses, Henry M. Hurd, M.D., 333. In memory of Silas Weir Mitchell, James J. Putnam, M.D., 821.
Adhesions. A study of some types of disturbance of the stomach and intestines associated with adhesions involving the intestinal tract and their treatment, Henry F. Hewes, M.D., 297. (See intra-abdominal folds.)
Alcoholism, 284.
Alien Insane in the civil hospitals of New York State, 698.
American Association of Physicians, meeting of, 809.
American Gynecological Society, 771.
American Society for the Advancement of Clinical Investigation, 809.
American Society for Control of Cancer, 743.
American Surgical Association, meeting of, 662.
American Posture League, 663.
American Neurological Association, meeting of, 809.
American Universities, relative size of, and medical schools in 1912 and 1913, 219.
Amputation at the Hip. A case of chondro-osteo-sarcoma, Robert W. Lovett, M.D., 511.
Anaimal Experimentation, an important trial on, 700.
Antityphoid Inoculation, vindication of, 626.
Antimeningococcic Serum, dangers in the use of, 1001.
Anti-Tuberculosis, the field of work of the Association, Seymour H. Stone, M.D., 691.
Anti-Vaccination, the Bagshaw Bill, 697, 808. Defeat of the Anti-Vaccination Bill, 847. Anti-vaccination sentiment in Germany, 926.
Appendectomy in a bleeder. Blood in vomitus and stools. Massive hematoma and ecchymosis. Recovery, Torr Wagner Harmer, M.D., 90.
Architecture of the Children's Hospital, Charles A. Coolidge, A.M., 481.
Army and Navy, typhoid in, 104; United States, medical status of, 855.
Arthritis, gonorrheal metastatic, H. W. E. Walther, M.D., 561. The importance of early recognition of acute arthritis of the hip-joint in infants, Arthur T. Legg, M.D., 527.
Aural Vertigo, D. Harold Walker, M.D., 791.
Auto-Serum Injections in chronic psoriasis and other obstinate skin diseases, 924.

Back Pain and its diagnosis, Harry Platt, M.D., 982.
Bacteria, transmutation and race-building among, 845. A practical method of drying cultures of, 894.
Bagshaw Vaccination Bill, 664, 808. (See vaccination and anti-vaccination.
Banti's Disease with report of successful splenectomy, Milton G. Sturgis, M.D., 832.
Bertillion, Alphonse, 364.
Bettinger, Julius, "(l'Anonyme du Palatinat)." 888.
Bilateral Sarcoma of undescended testes, Oliver C. Smith, M.D., 839.
Bichloride Tablets, federal or international regulation of, 282.
Blood. Appendectomy in a bleeder. Blood in vomitus and stools. Massive hematoma and ecchymosis. Recovery, Torr Wagner Harmer, M.D., 90. Recent advances in certain blood diseases, Roger I. Lee, M.D., 580.
Blood Pressure, the effect of digitalis on and pulse pressure in the presence of cardiac decompensation, Charles H. Lawrence, M.D., 37. The interpretation and management of low blood-pressure, 860.
Bone Cyst of the Os Calcis, a case of, William Pearce Coues, M.D., 611.
Bone Drilling and bone plating set, Louis A. O. Goddu, M.D., 52.
Boston Board of Health, reorganization of, 771.
Boston's Tuberculosis Death Rate decreasing rapidly, 211.

Marriage, medical certificate for, 28; and eugenics in Wisconsin, 104.
Massachusetts Conference on Tuberculosis, 587.
Massachusetts Anti-Tuberculosis League, 587.
Massachusetts General Hospital, neurological social service at, Margherita Ryther, 408.
Massachusetts Medical Society, special meeting of council, 73; stated meeting of council, 291, 964.
Massachusetts State Board of Health, reorganization of, 138, 324, 735, 934; an act to create a State Department of Health and to amend the public health laws, 817; an act to reorganize, 819.
Mayo-Gillium Operation, a further report on for retroversion of the uterus, Harold W. Baker, M.D., 89.
Mastoid, a radiographic study of the, Oliver A. Lothop, M.D., 343.
Measured Feeding for older children, Wm. R. P. Emerson, M.D., 86.
Medical Certificate, for marriage, 28.
Medical Examiners for Greater New York, 470.
Medical Inspection of immigrants, 661.
Medical Inspection of immigrants at the port of Boston, A. J. Nute, M.D., 642.
Medical Progress, See Progress.
Medical Schools, relative size of American universities and, in 1912 and 1913, 219.
Medical Legislation, the Bagshaw vaccination bill, 664, 808; bichloride tablets, federal or international regulation of, 282; the dental nurse bill, 771; the practice of dentistry in Massachusetts, 24; disclosure of professional information, 326; drug stores, the registration of in Massachusetts, 63; illegal traffic, suppression of in habit-forming drugs, 625; nurses, the registration of, 361, 398; the reporting of occupation diseases, 252; the practice of medicine and dentistry, 139; reorganization of the State Board of Health, 735, 846, 810; state registration in medicine, 469; the tuberculosis problem, 262; vital statistics, registration of, 325, 431; Massachusetts State Board of Insanity, 965; reorganization of the state board of health, 1000.
Medicine, the practice of, and dentistry, 139.
Meetings, in New York, 662.
Mental Hygiene Work, a program of practical measures for, Henry R. Stedman, M.D., 185.
Mental Diseases, report, on Henry R. Stedman, M.D., 274.
Mental Disorder, the treatment of cases of in general hospitals, Philip Coombs Knapp, A.M., M.D., 637.
Mental Efficiency, the dangers that attend the use of functional tests alone in, 212.
Mental Nursing, the art of companionship in, Henry R. Stedman, M.D., 673.
Mexico, preparations for military and naval surgery in, 699; medical aspects of the situation in, 734; medical situation in, 809, 887.
Midwife, in England and in America, 469.
Migrane, the relationship between epilepsy and, George A. Waterman, M.D., 337.
Military and Naval Surgery, preparations for in Mexico, 699.
Miscellany. Report of British Royal Commission of venereal diseases, 35; free public lecture on medical subjects, 36; report of committee on the standardization of hospitals, 71; Massachusetts Medical Society, special meeting of council, 73; a question of veracity, 147; United States mortality statistics in 1912, 183; relatiye size of American universities and medical schools in 1912 and 1913, 219; first national conference on race betterment, 219; a French female xiphopagus, 258; relationship of typhoid and tuberculosis, 259; Massachusetts Medical Society, stated meeting of council, 291; changes in the medical corps, U. S. navy, 331; United States Public Health service, 332; memorials, 447; International Surgical Association, 597; meeting on cancer, 598; another method of providing dental nurses, 634; the new Children's Hospital of Philadelphia, 671; non-vaccination and virulent smallpox, 672; experience with eugenics in Philadelphia, 707; infant mortality in New Zealand, 707; American Society for Control of Cancer, 743; transfer of Surgeon-General's Library, 743; Illinois state civil service commission, 744; a collection of Greek surgical instruments, 777; the maggot trap a possible solution of the fly problem, 778; Italian dentists and dentistry, 779; an act to create a State Department of Health and to amend the public health laws, 817; an act to reorganize the Massachusetts State Board of Health, 819; address to Dr. Walcott, 819; medical status of the United States army, 855; cancer meeting in Boston, 856; a practical method of drying cultures of bacteria, 894; United States mortality statistics, 895; an important sanitary problem, 1009; Yale medical school, 1011; wreck of a hospital ship, 1011.
Measles, its relation to oral conditions; with a clinical report of six cases, H. C. Hoye, D.M.D., 130.
Mitchell, Silas Weir, in memory of, James J. Putnam, M.D., 821.
Mortality Statistics, United States, in 1912, 183.
Muscles, relation of foot and leg to the statics of the body, C. L. Lowman, M.D., 191.
Myatonia Congenita, a case of (Oppenheim), J. W. Courtney, M.D., and H. B. Eaton, Cand, Med., 117.

National Association for Study and Prevention of Tuberculosis, 808.
Nasal Deformity, an operation for correcting the aquiline, the use of a new instrument, report of a case, Oliver A. Lothrop, M.D., 835.
National Conference, first, on race betterment, 219.
National Insurance in Germany, 27.
Navy, typhoid in army and, 104; preparations for military and naval surgery in Mexico, 699.
Neosalvarsan, the use of from a clinical and serological standpoint, J. Harper Blaisdell, M.D., 868.
Nephritis, some problems in, Horace D. Arnold, M.D., 601.
Neurological Social Service, Massachusetts General Hospital, Margherita Ryther, 408.
Neurasthenoid Conditions, chronic malarial cachexia and its relation to, Curran Pope, M.D., 193.
Neuritis, Brachial, report of a case of, due to periostitis of rib, R. W. French, M.D., 14.
Neurological Institute of New York, 886.
New Instruments, Bone drilling and bone plating set, Louis A. O. Goddu, M.D., 52; a new combination tonsil knife, Rockwell A. Coffin, M.D., 726.
Nitrogenous Metabolism in a case of chronic myelogenous leukemia, Harry W. Goodall, M.D., 789.
Non-Vaccination. See Vaccination.
Nursing, the art of companionship in mental, Henry R. Stedman, M.D., 673.
Nurses, educational standard for, state registration and training school inspection, Sara E. Parsons, R.N., 574; relation of the general hospital to the training school for nurses, Henry M. Hurd, M.D., 333; registration of, 361, 398; dental, another method of providing, 634.

Obituaries. Allan Foster Barnes, M.D., 671; Joseph D. Bryant, M.D., 634; Thomas Drusiyn Griffiths, M.D., 777; Egbert LeFevre, M.D., 597; Amos Lawrence Mason, M.D., 1008; Horace Eugene Marion, M.D., 368; Silas Weir Witchell, M.D., 182; Roswell Park, M.D., 331; Charles Pickering Putnam, M.D., 741; Thomas Morgan Rotch, M.D., 596; Edward Charles Spitzka, M.D., 147; George Henry Torney, M.D., 71.

CARBON MONOXIDE POISONING.

BY WILLIAM H. ROBEY, JR., M.D., BOSTON,

Instructor in Medicine, Harvard Medical School; First Assistant Visiting Physician, Boston City Hospital.

MOST writers on the subject believe that carbon monoxide poisoning receives but scanty attention from physicians, and this is probably so since the average physician of city practice sees but few cases. Edsall points out that carbon monoxide poisoning in addition to the acute illness and possible fatality which it may cause is also responsible for the production of certain subacute or chronic disorders, and Sedgwick considers the various obscure consequences as more important than the acute poisoning. Its sequelae are varied in nature and, unless the history of the acute poisoning is known, are difficult of interpretation. Acute poisoning with its sequelae has been, of course, much better studied than the chronic forms as it is difficult to prove that carbon monoxide has been the cause of conditions found in certain persons living under bad hygienic circumstances.

Professors Sedgwick and Nichols, in their excellent report on "Coal and Water Gas," as given in the Sixth Annual Report of the State Board of Health, 1885, mention the case of a lady in fair health who began somewhat suddenly to suffer from intolerable headaches. They were worse on awakening from sleep, and wore off gradually during the day to return on the following morning. After much effort to diagnose and control the headaches her physician was told of or discovered a faint odor of illuminating gas in the room. A leak was found in a pipe running under the floor, and when it was stopped the patient quickly recovered. This was one of the simpler forms of poisoning from illuminating gas which would not be so obscure if one had the cause in mind.

Another source of poisoning is the escaping of gas from broken mains in the earth and thence into houses. This is particularly so in winter when the ground is frozen and perhaps covered with a coating of ice. Even if the ground is bare, the temperature of the houses is considerably above that of the outer air, converting them into so many chimneys to which the air in the ground is drawn from all sides. Leaks and resulting poisonings of this nature are much more obscure and difficult of solution. Pettenkoper has shown that the gas may travel many yards through the ground and reach a dwelling a considerable distance from the leak, while the odor is lost in transit. This method of producing carbon monoxide poisoning probably forms now but a trifling per cent. of the cases and is almost disregarded by the majority of writers since Pettenkoper's time.

Sedgwick recently has called attention to the insidious effects of constantly inhaling illuminating gas in houses and public places. The intoxication by carbon monoxide in factories and foundries is not uncommon, but this paper is not concerned with poisoning produced by manufacturing processes.

It is believed that obscure poisoning of various kinds plays a large part in diminishing vital resistance and in increasing susceptibility to disease. The number of acute cases is ever increasing. There are many reasons for this, such as the greater use of household appliances for cooking and heating, especially when they are used in small and ill ventilated rooms. Professor Sedgwick in a recent article in the *Journal of Infectious Diseases*, November, 1911, on "The Relation of Illuminating Gas to Public Health," calls particular attention to the increasing manufacture of water gas as the cause of a great number of carbon monoxide poisoning cases in recent years. In 1884 Professors Sedgwick and W. R. Nichols and Dr. Samuel W. Abbott predicted that if water gas should replace coal gas in Massachusetts the consequence to public health would probably be dangerous if not disastrous. Other experts of eminence took precisely the opposite ground and even ridiculed the possibility of any such consequence. Among these were Professor C. F. Chandler of Columbia University and the distinguished English chemist, Dr. E. Frankland, who stated in a letter read during the hearings, "I have no hesitation in saying that it (water gas) may be used with safety both in public buildings and private houses. I should be delighted to substitute this pure and powerful illuminating agent for the gas with which my house in London is at present supplied, although it is used in all the bedrooms."

Previous to 1885, according to Dr. S. W. Abbott, there had been only four deaths during twenty years in Massachusetts. It is a question how much reliance can be placed on this statement because of imperfect methods of recording cases. As a result of the coal and water gas agitation the Massachusetts Legislature in 1885 created a State Gas Commission and since 1888 the Commissioners have been required to keep a record of all fatalities and other subsequent results from gas poisoning.

Let us pause for a moment at this point to consider the nature of coal and water gas. Poisoning from pure carbon monoxide is extremely rare, because opportunities for its occurrence are unusual; it has occurred in laboratories and factories.

Intoxication with illuminating gas is commonly regarded as being practically carbon monoxide poisoning, but experiments have shown that its poisoning is usually more severe than from simple carbon monoxide. Nevertheless, the latter is the chief agent.

Illuminating gas is poisonous whether made from the destructive distillation of bituminous

coal, from wood or other organic substances, or derived from coal and water by their action on each other at high temperatures (water gas). It is, nevertheless, a single gas of uniform composition, and while the mixture may vary from day to day within narrow limits, the expressions "coal gas" and "water gas" stand for a reasonably definite substance or mixture. Various analyses by different chemists have shown that water gas contains about four times as much carbon monoxide as coal gas. The amount of carbonic oxide requisite to produce a fatal result varies considerably with different individuals. A variety of conditions enters into this factor. Carbon monoxide enters the system solely by inspiration unless experimentally introduced. Its chief effect is to displace the oxygen from oxyhemoglobin and form carbon monoxoglobin, thus rendering the affected portion of the red blood corpuscles incapable of performing their function as oxygen and carbon dioxide carriers.

Sedgwick and Nichols carried out numerous experiments on the relative effects of coal and water gas on animals. Their experiments and conclusions are given under four headings:—

1. With ordinary gas fixtures it is generally difficult to get more than three per cent. of illuminating gas into an ordinary room. By using one burner alone, it is difficult to exceed one per cent. The "natural ventilation" through walls and cracks is the reason for this.

2. With coal gas it is a matter of some difficulty to get into an ordinary apartment through the ordinary burners gas enough to produce upon healthy animals distinctly poisonous effects. With water gas, on the contrary, it is comparatively easy to get into an ordinary apartment through the ordinary burners gas enough to produce poisonous and even fatal effects. The same quantity of gas would be present in the room in either case. Water gas does not flow more freely or accumulate in the room any more than coal gas.

3. It does not follow that because one illuminating gas contains three, four or five times as much carbonic oxide as another that it is, therefore, only three, four or five times as dangerous to life.

4. Carbonic oxide is not a cumulative poison. That is, the breathing of a small quantity for a long time is not equivalent to the breathing of a large quantity for a short time. A similar conclusion may be drawn in all the constituents of illuminating gas. These authors state: "From the fact that carbonic oxide is not a cumulative poison and from the considerations concerning the rapid increase of danger above and the decrease of it below the 'danger line,' it follows that within certain limits the less carbonic oxide there is in illuminating gas the safer it is for public use, for about the danger line a very moderate decrease of carbonic oxide may very greatly enhance its safety, while a moderate increase may greatly multiply the dangers arising from its use. Far above and below the danger line the effect of slight variations is very little."

The record of the experiments with animals conducted by Professors Sedgwick and Nichols to prove the above conclusions may be found in the Sixth Annual Report of the State Board of Health.

Since 1890 the careful records of the State Gas Commission and the Medical Examiner's office show that more than 1,200 deaths from carbon monoxide poisoning have occurred in Massachusetts in a twenty-year period from 1890 to 1909. Sedgwick and Schneider in their recent article in the *Journal of Infectious Diseases* have compared the mortality from scarlet fever, measles and illuminating gas in Massachusetts for a period of twenty years. For example, the death-rate was:—

	Scarlet Fever	Measles.	Illuminating Gas.
1887	28.80	22.08	0.29
1898	5.25	2.05	2.91
1909	7.86	4.77	3.10

I have merely shown the changes at the end of two ten-year periods—the authors give the death-rate for each year in tabular form.

Since 1890 some companies have made only water gas, others only coal gas, while many have made a mixture of the two, and some have made both intermittently. For a short time (1900) the amount of water gas manufactured was much less, and there was a corresponding diminution in the number of gas poisoning cases. Sedgwick and Schneider give an interesting table derived from the Reports of the Gas Commissioners showing the amounts of illuminating gas (coal gas and water gas) manufactured each year in Massachusetts. Figures in this table show a marked increase in water gas and a corresponding increase in the number of deaths. In 1886 the total coal and water gas made in million cubic feet was 2,625, and water gas 12, with no deaths. In 1896, total 4,639, water gas 3,090, and 63 deaths. In 1908, total 10,902, water gas 4,862 and 148 deaths. In 1900 and 1901 when the New England Gas and Coke Company installed a large coal gas plant in Everett, the effect of the introduction of their product was to cause an actual decrease in the water gas manufacture in the state and in 1901 a significant diminution in the number of deaths from gas poisoinng.

There were 174 cases of illuminating gas poisoning admitted to the Boston City Hospital from 1900 to 1910 inclusive. Of this number, 35 had a definite history of attempted suicide, and 27 had been drinking more or less heavily before the accident; 8 gave a history of being overcome while at work, principally in trenches; 2 cases were due to slot gas machines, the persons going to bed with the gas lighted, the gas giving out in the night but being started up in the early morning by somebody depositing the requisite coin. There were half a dozen cases of blowing out the gas, this accident occurring with

foreigners of the peasant type recently arrived in America. Most of the non-fatal cases fully recovered in from two to four days. In cases that recovered from coma in two to four days and then died, the death was usually caused by pneumonia or by some pathological condition which had existed prior to the exposure and which was precipitated by the gas poisoning. All of the nineteen cases in this series which died were accidental as far as could be ascertained. No one of the 35 cases of attempted suicide proved fatal. Eleven died from gas poisoning without complications, three cases were complicated by pneumonia, two by burns, one by uremia and one by cerebral embolus. With reference to the subsequent effects of acute gas poisoning, we have been unable to find the record of but three re-admissions, all men and admitted for alcoholism.

It would be natural to ask how it is that the Boston City Hospital had only 174 cases admitted in eleven years when in the year 1910 alone there were 80 cases of gas poisoning in the city of Boston. It is probably the only point which this paper will show, viz., that with the appalling number of cases as shown by the Report of the Gas Commission of Massachusetts so few ever have a chance for treatment because of immediately fatal results. Forty-two of the 80 cases in Boston in 1910 died, leaving 38 non-fatal cases, 21 of whom were received at the hospital.

The crux of the matter is that the increased amount of carbon monoxide in water gas makes a small volume of gas fatal in a much shorter time. Coal gas by its very strong odor made its presence known sooner to other inmates of the house, and while the victim might be unconscious when found, he had not as a rule inhaled sufficient carbon monoxide to make treatment useless.

A comparison of figures shows that with the large amount of water gas, containing about four times as much carbon monoxide as does coal gas and having a less striking odor, many victims are fatally poisoned by a volume of gas which in the same cubic space and length of time would have resulted only in unconsciousness and are therefore dead or nearly dead when found.

The cases were as follows:—

	Admitted to the Boston City Hospital			In Boston and Suburbs					
				Fatal Cases			Non-Fatal Cases		
	Males.	Females.	Total.	Males.	Females.	Total.	Males.	Females.	Total.
1900	5	1	6	21	3	24	19	6	25
1901	13	6	19	16	0	16	159	4	163
1902	5	7	12	25	3	33	49	7	56
1903	8	9	17	20	6	26	25	25	50
1904	9	5	14	22	2	24	19	9	28
1905	8	1	9	22	6	28	22	11	33
1906	10	4	14	17	14	31	28	15	43
1907	9	8	17	45	25	70	32	15	47
1908	21	8	29	26	16	42	33	9	42
1909	13	2	15	36	8	44	22	14	36
1910	13	9	22	36	9	45	33	10	43

The seasonal distribution was as follows:—

January	15	July	2
February	10	August	7
March	16	September	9
April	19	October	15
May	11	November	18
June	9	December	40

In most of our cases the patients felt a sense of drowsiness, to which they yielded and could tell nothing more about themselves. A few complained of headache and most all had severe nausea and vomiting. Some noticed the odor of gas in the room, but paid no attention to it and remembered nothing else until they recovered consciousness in the hospital.

A rather large number of the cases have this record:

Skin mottled and lips and lobes of the ears cyanosed. Unconscious; stertorous respiration; involuntary dejecta; odor of gas on breath. In one case the urine drawn by catheter had a strong odor of gas. The eyelids react when the lashes are touched. Conjunctivae suffused. Pupils contracted but react to light. Eyeballs immovable. Teeth slightly clinched. Mucus on lips. Arms slightly flexed at elbows. In one case which showed the above signs, the man had gone to bed with the gas lighted in a house supplied by a slot machine. At five in the morning, another inmate put a quarter in the machine and the patient was found at seven o'clock in the condition as detailed above. The gas company estimated that from 3 to 3.5 feet of gas had escaped into the room. The patient was mentally confused for several days but was discharged well after remaining nine days in the hospital. Case 11 showed rigid flexion of forearms and wrists and the feet in plantar flexion.

Most of this series where there were marked reflex changes the patients were suffering from organic nervous disease before the gas poisoning.

Treatment. Prophylaxis is of the greatest importance. Sedgwick and Schneider think that we should return to the use of coal gas exclusively, believing that with its much lessened power to poison, the majority of cases would be discovered in time to save their lives. Even if one-half of the deaths are voluntary or suicidal, as physicians we cannot overlook this part of the question. Within the last few years the state of Massachusetts has sought by law to regulate the sale of poisons and firearms, and may well regard with concern the general distribution to the public of a dangerous gas so readily available for self destruction. It has been argued even by some excellent physicians that persons who have once displayed a suicidal intent may as well not be thwarted since sooner or later they will carry out their design. We all know of young persons who during a temporary despondency have considered suicide—the thought may never occur to them again, but if a too easy means is at hand they may yield to the impulse. We know of many persons who have confessed that they have considered suicide at some time in their lives. Again, when a form of suicide is vividly detailed

by the press, repetitions occur for a time in various parts of the country.

In the treatment of acute poisoning, the cases received principally local heat, fresh air and cardiac stimulation. In a good many cases oxygen was given, although some authors regard it as useless. In a few selected cases venesection was used with apparent relief. Cardiac stimulation was given when necessary.

I wish to express my thanks to the visiting staff for the privilege of referring to the cases, and to Dr. T. Leary, medical examiner for Norfolk County, for helpful suggestions.

OLD AND RECENT IDEAS CONCERNING TREATMENT OF FLAT-FOOT.

BY H. W. MARSHALL, M.D., BOSTON.

THE importance of foot defects, included in the class of strains and weaknesses of the feet, can be appreciated properly only from the enormous numbers of persons who are wearing orthopedic appliances or shoes of orthopedic design. Arch supports, shoes with correct shapes, shoes with flexible shanks, others with rigid shanks, and shoes with heels or soles constructed to alter the position of the feet in weight-bearing attitudes, are very familiar now in many stores in all large cities.

Additional interest is lent to the present situation by the circumstance that wear of these special shoes and supports is determined now more by business enterprise, and by fancies of customers, than by medical advice and supervision. This condition of affairs has arisen naturally because such foot ailments in the majority of instances are not very grave in character. The general public is free to choose without medical opinion, and with good success very often, such kinds and varieties as appeal to their fancies, or those styles which friends have found to be beneficial.

Orthopedists and some enterprising shoe men during the period of development of new ideas about flat-foot have studied the anatomy of the feet again with care, so that nearly all important pathological changes have been described now in great detail.

It is very generally known there are longitudinal and transverse arches in the feet that can become weakened. The anatomical arrangement of the small bones of the feet, their normal positions and pathological variations have been examined; and it is well understood that, when weight is borne, pressure from above tends to push the astragalus downward and inward as it rests upon the os calcis beneath. Also that there may be considerable tilting of the calcaneum when the bones of the leg, with the astragalus, in bad cases of flat-foot, tend to slip down off the inner side of the foot until they are checked by ligaments and muscles, and as the foot tends to slip forward.

It is a familiar fact that these tendencies are resisted by the calcaneonavicular, the deltoid and the interosseous ligaments; and that when marked relaxations occur considerable slipping in the astragalonavicular joint takes place and that the scaphoid bone becomes very prominent. It is also known that other small joints of the tarsus are influenced in lesser degrees.

In typical flat-foot the front of the foot is forced outward and downward. The internal malleolus is more prominent, and motions of the feet are restricted. Adduction of the forefoot becomes greatly restricted, plantar flexion is limited, and dorsal flexion appears increased.

Special studies have been so numerous that a few of them only can be mentioned. R. B. Osgood[1] has studied, among other things, the strength of muscles in normal and weakened feet. He concludes that the adductors of the feet are stronger than the abductor group in normal persons, and he found in acute flat-foot that the normal average ratio of strength, 10:8, became 10:12 in weakened feet. Lloyd T. Brown[2] has considered the action of extrinsic and intrinsic muscles of the foot from an anatomical and mechanical standpoint. And the studies of Whitman, Lovett, Dane, Legg, Cotton, Feiss, Gibney, Thomas, and many others are too extensive and too important to be enumerated briefly.

It has been shown that the first metatarsal bone with its phalangeal bones is most important in locomotion, while the outer metatarsals are essential in maintaining the balance when standing.

In text-books, Whitman,[3] Goldthwait, Painter and Osgood,[4] Bradford and Lovett,[5] and others have described the two-fold function of the foot as a passive support of the weight of the body, and as an active lever to raise and propel it. And they have explained the many anatomical details which relate to development of weakness and deformities. Deformed feet of the Chinese have been made objects of study; and great attention has been paid to normal shapes of normal feet in the barefooted races. Anatomical dissections have been made which show that gradual anatomical changes in the bones take place, as the bones adjust themselves to new conditions long imposed upon them. It is now well understood that shapes of shoes have much to do with development of weaknesses and strains, that extreme styles in pointed shoes in the past contributed perhaps as much as any one thing in calling attention to foot defects, and in leading to corrections in footwear. It is known that present styles of high heels are throwing disproportionate pressures upon anterior arches, and that the latter in consequence are giving out more frequently now. It is known that, notwithstanding the fact persons possess high arches, that they suffer frequently with foot strains; and causes of foot strains, as mentioned in text-books of orthopedic surgery, are described as being

due to faulty footwear; occupations that compel unusual amounts of standing; injuries, especially fractures of leg bones at the ankle that result in subsequent abnormal pronated positions of the feet; genu valgum; debilitated states; rachitis; great increase in weight, etc.

However, in spite of the precise knowledge which has accumulated, there still are a very considerable number of persons who are made worse, instead of better, by wearing shoes of orthopedic shapes. Others are made worse by shoes with flexible shanks, many are not improved by arch supports, and some continue to have weak feet after trying all methods now in use.

These facts are as well established as the ones that many individuals are benefited; and unfavorable results need understanding if successes are to be attained with more uniformity. The first important reason for failure lies in the circumstance already mentioned, e.g., that wearing of orthopedic shoes and supports often is dependent simply upon whims of customers, upon experiences of their friends, upon persuasions of persons selling the articles, instead of upon physiological requirements of individuals' conditions. A second reason lies in the failures of physicians to understand precisely the needs of their patients; and it is interesting to trace past developments which have led to present medical ideas.

When attention was first drawn to the barefoot tribes, it was seen that forms of their feet differed materially from those found in persons who have been cramped always in shoes. As a result of these observations, correctly shaped shoes were constructed with broad toes and with room for expansion of the anterior part of the foot, and especially to avoid outward deflection of the great toes. And then it was found that some persons with very deformed feet were unable to walk in these improved styles. They were more comfortable in their own improperly shaped ones.

Long subjection to tight shoes had changed bones and ligaments structurally, so that normal shapes were as injurious to these persons as modern styles would be to savages. It came to be realized then that many individuals are no longer predatory savages, as regards their feet; and that it is necessary to fit them with shoes suited to their existing deformities. Physicians learned that in extreme cases natural shapes could be restored only very gradually, and that consideration of other factors besides forms of footwear must be kept in mind. Some foot deformities now are recognized to go so far as to necessitate forcible manipulations and operations to restore even approximately normal conditions again.

With arch supports there has been a similar negative phase in progress; and from the positive benefit which many persons have derived, others have been induced to try supports with unfavorable results. It has been found that persons with acute foot strain frequently have so much tenderness that additional pressures upon the arches cannot be endured. Others are relieved for short times, and then have slow return of painful symptoms from muscle weakness. Frequently the latter are benefited by minimizing instead of increasing artificial aids, and by exercising the feet with flexible shoes.

Flexible shoes consequently have been tried in routine manner like shoes with orthopedic shapes and as arch supports have been used; and many persons have been relieved by them, while many others find that they cannot wear flexible shoes.

From these various groups of cases, and from advocacy of single routine forms of treatment, have arisen partisanships which convincingly show that numerous deficiencies still exist in our understanding of flat-foot. There is need for understanding that physiological considerations, more than anatomical or pathological ones, furnish final solutions for difficulties in treatments. Treatments primarily should be designed to remedy physiological defects ahead of anatomical ones, although the latter must necessarily be corrected when they exist, because they prevent restoration of normal functions.

Structural defects are causes of present and future functional abnormalities, and simultaneously also they represent results of past physiological defects or primary congenital peculiarities. These more remote causes must be sought for, as it is possible to have perfect understanding of all anatomical peculiarities and of all pathological appearances, and yet be unable to deal with patients successfully when there is lack of understanding of underlying physiological forces which regulate health and weaknesses.

There ought to be unhesitating recognition that normal conditions in feet depend always upon a combination of elements, and never upon any one of them independently. These underlying factors are grouped into three divisions: first, the amount of weight borne and the lengths of times it is endured; secondly, the degree of healthy vitality existing at the particular time in ligaments and muscles supporting the arches that is represented by their strength; and thirdly, favorable and unfavorable qualities of blood circulating through the feet at the given time. This is the only working formula that is applicable universally to all cases, and it should come to mind as the most practical way of viewing each patient, instead of by special features alone in each one, such as shapes of feet, height of arches, occupations, body weights, physical conditions, etc.

All the latter considerations must be thought of, however, yet ideas of treatment must not stop at that stage for best results. These special details of each individual case should be fitted into the general comprehensive idea of the whole situation which has been stated. Broad comprehensive qualities are features in treatments that are often lacking, and it is purely a

matter of chance at present with many persons whether their shoes and supports are suited to their needs. Chosen without medical advice, and unnecessarily tried in many instances through curiosity rather than actual need, footwear and orthopedic appliances are worn frequently in complete ignorance of unfavorable consequences which are possible, the only guide observed being the degree of temporary comfort afforded. Yet practically it has been found that many persons are benefited for a time at least, although they have no ideas of physiological ways in which feet maintain their strength and function. And the principal complaint made by such persons is that they become very dependent upon arch supports, and that their feet become weakened by continued use of the latter.

The proper view to take toward various orthopedic devices and shoes is one of recognition that most of them have merits, and that they indicate the number of phases which any single case may pass through. This seems to be the correct idea in contrast to the erroneous one that some devices must be useless or harmful because some others are beneficial. For faults do not lie with shoes or supports as much as in defective understanding of conditions which lead to their inappropriate uses. All devices may be beneficial or harmful in turn in any selected case according as they are prescribed, or accidentally happen, to fit the needs that exist and that vary from time to time.

Indications and contra-indications can be determined, however, usually very easily from the general conception that has been stated. Health always represents a balanced state between various physiological elements; and treatments are directed always toward restoring usual ratios between these several forces. In health, if persons become heavier, then compensatory changes in strengths of muscles and ligaments are seen so that normal balances between pressures upon arches and muscle strengths are not upset. If the individual is very large instead of very small, then changes in absolute strengths of muscles and ligaments have, too, to be very great instead of small, in order to maintain the healthy balance. Absolute values of the same factor in different persons may vary within wide limits and yet be relatively unimportant. The most vital relationship always is the ratio between the different factors as they are combined in the same person. In order to restore normal conditions in weakened feet, pressures and strains, that are endured, can be diminished by supporting the arches or by subjecting them to less mechanical strain by rest, or by combining supports with partial rest.

Usually it is more convenient to begin treatment by increasing supports instead of diminishing amounts of daily activities of life. The ways of strengthening the arches are familiar. They may be artificially held with adhesive straps which extend around the sole of the foot upward upon the two sides of the lower leg, so that a part of the pressure upon the arches is taken by the pull upon these leg straps. Felt pads, spring steels, celluloid, rubber, and other varieties of support have been used. The strength of the foot may be increased also at times by regular exercises or by wearing limber shoes which, unconsciously to the wearer, exercise foot muscles more than when they are supported by thick soled boots. Improved shapes in shoes indirectly may help to strengthen the feet by allowing more natural shapes to be restored.

There is no certain way of estimating which variety of treatment will prove most beneficial except by a few simple preliminary trials with supports of some sort, alternating them with exercises; but these quickly furnish the required information.

Usually persons who walk and stand very little, and who have been wearing heavy soled shoes or supports constantly will be benefited by flexible shoes and by diminishing artificial aids, provided blood conditions remain unchanged. And vice versa, persons who use their feet continually, or have worn very thin shoes, will find temporary relief in thicker shoes and more support. Both may be followed by return of symptoms if they are long continued; and changes from time to time ought to be made, if physiological needs are to be perfectly met. A constant feature of all cases is the one that artificial aids ought to be kept down to a minimum degree from time to time; and the feet should perform their functions always as nearly normally and unaided as their strength permits. Whether patients with weak feet shall be kept off of them a part of the time, or completely, can be told from experiment and from indications furnished by the past history; and these trials should be made and right amounts quickly estimated. Changes that have to be made in these mechanical elements may vary from no change at all to complete rest in plaster casts; but in every case the mechanical factors should be thought of at least although nothing has to be done.

Vascular elements in development of foot strains are ones most commonly poorly understood, despite the fact they undoubtedly are as important as mechanical features. It is possible, though rarely advisable, to cure pains in the feet from the lesser degrees of foot strains simply by medicinal tonics, iron, cathartics and eliminants without paying attention to local conditions. This medical phase of treatments, however, is lost sight of at present very commonly in search for local anatomical defects; but the important influence of vascular states is convincingly indicated nevertheless by the frequency with which debilitated conditions initiate development of foot symptoms. Debility is a matter orthopedists, as a class, have rather vague ideas about, dealing as they do mainly with tangible mechanical devices and anatomical considerations. Debilitated states are poorly

understood by all, yet there are a few rough quantitative defects in normal physiological processes which are recognizable, and which can be corrected frequently with good results.

It is known that digestive disturbances are starting points for many troubles. Normal digestive functions frequently become temporarily poor through fatigue or worries; and ordinarily harmless products of intestinal bacterial activity become increased temporarily from increased bacterial action upon the food residues left as a result of poor digestive function. Larger quantities of bacterial products than usual are absorbed in consequence, and circulate in abnormal amounts, exerting mild deleterious influences, and show themselves finally in the fluctuations of indican and allied substances in the urine. The blood stream temporarily has slightly changed proportions among its usual constituents, and if these fluctuations are repeated often, or continue long enough, they give rise indirectly or directly to mild anemias, articular pains, etc., etc. Individuals feel below their usual standards, muscle tone is lessened, and weaknesses become accentuated. Feet frequently suffer in this way; and the remedy primarily consists in diminishing amounts of useless substances in circulation by diminishing absorptions from the intestinal tract and by increasing their eliminations. This is accomplished with the aid of stimulating tonics to increase normal digestive, peristaltic and cardiac functions, by cathartics to remove food residues promptly, and by increasing the excretion of urine. Iron in some form is beneficial simultaneously to correct deficiencies that have arisen in the iron content of the blood.

These are extremely well known measures, but their importance in treatment of many types of flat-foot the writer has seen repeatedly overlooked. Many patients have been treated with strappings, plates, shoes, Thomas heels, etc., and have dragged along without being crippled, and yet without recovering their normal strength; and then, when a few weeks' attention has been paid to defects in circulating blood, normal conditions have been restored again promptly. Prescription of drugs cannot be made in haphazard ways, and their effects have to be watched as carefully as those of mechanical appliances in order to rectify the defects in alimentary tract and circulation that are producing the slightly unfavorable conditions. When it is remembered that every person's start in life begins with certain initial vitalities in each organ and in every living cell, as well as in all collectively; that these initial vitalities vary in different persons and that the blood is the common soil in which all tissues grow, then it can be realized that what is brought to, and what is taken away from, living cells by the blood stream constitute the most important influences to which tissues are subjected. If proportions of substances in circulation remain constantly favorable the individual thrives, and may grow strong and robust even from a very poor beginning; and vice versa, unfavorable quantitative proportions of vascular substances soon produce delicacy and debility in persons originally strong, as a barren soil always produces scanty crops. What is true of the person as a whole is true of his organs individually. Some organs are stronger and better developed than others at birth and often keep their lead throughout life; and if vascular conditions are unfavorable for ligaments and muscles, then these show the effects of the unfavorable influences in drooping attitudes, round shoulders, weak backs, flat feet, visceral ptoses, etc., so commonly observed. Knowledge of these changes in the blood from time to time, also the biological needs of living tissues are the matters that should have more universal understanding now when anatomical details of foot structure have been so thoroughly investigated. Some types of flat-foot, however, must be recognized to be almost, or entirely, beyond control when chronic progressive diseases of the gastro-enteric tract, kidneys, or other organs prevent correction of vascular conditions. This is true although harmful mechanical pressure and strains always can be perfectly eliminated and controlled. Patients with flat-foot in the future probably will select their own supports and shoes very frequently without advice, as now; but when they consult physicians they should receive directions that are based upon physiological principles as well as upon pathological changes. Then patients will be made to realize that no one style of shoe, or principle of treatment, is universally applicable, and that their needs necessarily change from time to time, so that a number of entirely different measures are likely to be tried before normal balance between blood, mechanical pressures, and tissue resistances is again restored.

Too much cannot be known about anatomy and pathology, yet it should be remembered that of themselves, they offer only incomplete suggestions as to proper treatments; and equally important physiological and biological needs must be understood and familiarized before functional defects can be perfectly corrected.

—At the ninth annual meeting of the American Red Cross in Washington, announcement was made of the completion of the $300,000 fund, which was necessary in order to secure the $400,000 appropriated by Congress for the erection in Washington in memory of the women of the Civil War of a building to be used as headquarters for the Red Cross. This assures erection of the memorial at an early date.

Medical Record.

HAIR CAST OF THE STOMACH WITH REPORT OF A CASE.

BY G. A. MOORE, M.D., BROCKTON, MASS.

Of the pathological curiosities found in man, no region has yielded such an abundance as the gastro intestinal tract. The most remarkable of these are the foreign bodies, especially those found in the stomach; an enumeration of which would fill a small volume. These objects vary in size from pins, nails and screws to ketchup bottles and masses of roots and hair weighing several pounds.

With the exception of objects found in the stomachs of professional glass-eaters, knife swallowers, etc., foreign bodies may be divided roughly into two classes: First, hard objects, such as knives, spoons, nails and screws, found almost exclusively in the insane; and Second, those composed of roots, strings, rags and hair, discovered in patients a great proportion of whom are mentally sound.

To this second class of cases and especially to the foreign bodies composed of hair this paper will be limited, including a report of a case.

While these cases are not common, they can hardly be considered of rare occurrence, for after a fairly exhaustive search, the writer has found 53 mentioned in the literature.

The occurrence of bezoars or hair balls in the human stomach might well be used as an argument in favor of evolution, as they are frequently found in animals in the season when the hair is shed. In animals, however, except in certain breeds of Angora cats, serious symptoms are never observed, since the masses are usually much smaller than those found in man, and are firmly felted together, due to the projection of the outer layer of epithelial cells on the hairs. They are frequently expelled in the vomitus or feces covered with a thick coating of food particles and mucus.

In man felted masses are rarely observed, since human hair is much smoother than that of animals. The hairs are loosely woven or matted together with food particles caught in the meshes. It is probably due to the loose arrangement of the hairs; that symptoms of pyloric obstruction are rarely if ever encountered; the food either being filtered through the mass of hair or pushed past it.

Another class of foreign bodies found in sane patients merits consideration. These are the so-called gastroliths or bodies found in the stomach as a result of drinking varnish, shellac, etc., to satisfy a craving for alcoholic drink. The occurrence of gastroliths is very rare indeed as compared with hair balls. Early operation is, however, more frequently necessitated, owing to ulcerations and symptoms of obstruction.

Case. A. B., 28 years old. Shoe factory worker. Referred to me by Dr. W. H. Pulsifer, Whitman, Mass., March 13, 1912.

F. H. Unimportant.

P. H. Had all children's diseases. Never had diphtheria, pneumonia or typhoid. Always well up to six years ago when she states she contracted syphilis. Bore two healthy children prior to 1906. The first one died of marasmus; the second, of ileocolitis. (Both died at Boston Children's Hospital.)

In 1906 a third child was born which was said to be syphilitic. Since 1906 she has occasionally noticed a rash over her body and sore spots in her mouth, nose and scalp. Has had many self-induced abortions, the last one occurring in December, 1911. Had very severe abdominal pain and high fever following last abortion, since which time she has had considerable pain and burning on micturition and frequent attacks of pain in both lower quadrants of abdomen. Catamenia: Began at 14; always regular and copious. Constant leucorrhea since 1906. Appetite always good up to beginning of present illness. No digestive disorders.

P. I. About Jan. 1, 1912, began to complain of pain in right side of abdomen on level of umbilicus, which frequently radiated over entire right side of abdomen and chest. Pain often so severe that patient was unable to breathe. The pain was never localized in the epigastrium. Soon after onset of the present illness, patient noticed a mass in abdomen just to right of the umbilicus, about the size of an orange, which has gradually increased in size. She has had frequent attacks of vomiting, lasting a few hours, at times before eating, at others, after. Vomitus frequently composed of "white slimy stuff," occasionally dark and frothy. Bowels constipated, no noticeable change of late. Usual weight 115, present weight 96.

P. E. A pale, sickly, emaciated woman, apparently suffering severe abdominal pain. Skin dry and parched, scalp clean, no ulcerations. A few small pigmented scars over left thigh and both tibiae. Pea-sized glands in left cervical region and both groins. Teeth: Upper false, lower in fair condition. Nose normal. No ulcerations. Eyes: Pupils equal, regular and react normally. Tongue clean, mucous membrane of mouth and throat pale but otherwise normal. Nothing abnormal found in lungs. Heart normal in size, sounds normal, except for slight systolic murmur at apex not transmitted. Abdomen: Moderately distended, but lax and tympanitic throughout. Moderate prominence in left hypochondrium. Moderate diastasis of recti. Considerable tenderness without spasm or rigidity over entire right side of abdomen and left hypochondrium. On palpation a very firm, rounded, movable and extremely tender mass was found extending from one and one-half inches to the right of the median line just below the level of the umbilicus to the left beneath the costal margin. The upper border of the mass was two inches below the xyphoid cartilage, the lower border one and one-half inches below the umbilicus, roughly three and one-half inches vertically by six inches transversely. On standing the entire mass sank lower down in the abdomen and extended further to the left. (See Fig. 1.)

In the dorsal position the tumor could be moved to right or left so that the fingers could be inserted between it and the costal margins. Liver dullness normal. No hilum could be felt in tumor. Splenic dullness normal. Kidneys not palpable. On careful palpation over the tumor a sense of crackling or deep crepitation could be made out. Pulsations of

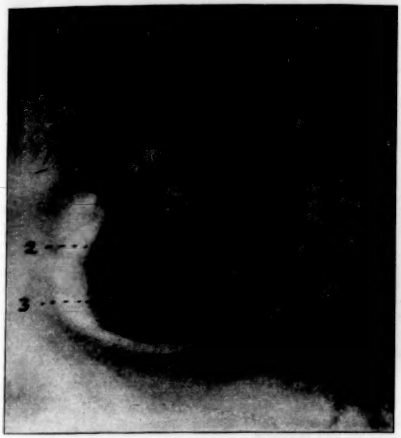

FIG. 1.

Patient standing.

1. Ensiform.
2. Umbilicus.
3. Black line indicating right and lower border of tumor.

aorta apparently transmitted through the mass, no expansile pulsations or bruit.

Vaginal Examination. No cicatrices or ulcerations observed about vulva or vaginal walls, moderate leucorrhea, cervix bilaterally lacerated, uterus normal in size, freely movable, retroflexed into hollow of sacrum. Knee jerks normal.

A provisional diagnosis of tumor of syphilitic origin was made and the patient put on iodides, which were pushed to the limit of tolerance. Under this treatment there was an apparent increase in the size of the tumor and the patient lost ground. Operation, which was at first refused, was finally consented to and the patient entered the Brockton Hospital July 7, 1912.

Physical Examination on entrance was practically the same as four months previously, except that the tumor was larger, extended further to the right and was more freely movable. Just to the right and above the umbilicus was a small area of tenderness. Over no other part of the mass was any tenderness elicited. The stomach was inflated and the lower border found to be two inches below the umbilicus while the upper border was in normal position.

Patient was put on house diet and had no gastric symptoms except a slight attack of nausea and vomiting after eating oranges. This she stated was a common occurrence.

Temperature, pulse and respirations normal. Urine normal.

Blood. Hemoglobin 70% Tallquist, white count 12,000, red count 5,300,000. Smear: Moderate achromia, otherwise normal. Differential count: Polynuclears 63%, lymphocytes 35%, transitionals 2%.

Wassermann and Noguchi reactions strongly positive.

The diagnoses considered were: (1) Mesenteric tumor of specific, malignant or tubercular origin. (2) Omental tumor. (3) Spleen. (4) Kidney. (5) Fecal impaction. Of the provisional diagnoses a malignant tumor of the mesentery seemed the most probable in view of the fact that it had increased in size under forced antisyphilitic treatment. Gumma of the mesenteric glands was the next choice. Omental tumor was thought to be improbable as there was tympany over the entire tumor. Spleen was ruled out by absence of a hilum in the tumor and by the presence of normal splenic dulness.

A kidney would hardly be as freely movable nor would there be tympany over the entire mass. The firm consistency, form and absence of pitting on pressure, ruled out fecal impaction.

The patient's general condition had not improved in the four months she had been under observation, the tumor had increased in size and she still complained of occasional pains in the right hypochondrium. Exploration was advised in the hope of finding an operable condition.

Operation July 19, 1912. Dorsal position, five-inch median incision from xyphoid to below umbilicus. Peritoneum opened revealing normal omentum. Mesentery and transverse colon normal. Nothing abnormal in gall-gladder and ducts. Spleen normal. Stomach: upper border in normal position, lower border about two inches below umbilicus, apparently completely filled by a large, smooth, sausage-shaped mass roughly nodular near the pylorus. Stomach was partially delivered from the abdomen and carefully walled off. Silk stay sutures were then placed in the anterior wall and a three and one-half inch incision made between the stays from the lesser to the greater curvature of the stomach about three inches from the pylorus. Through this opening the tumor, which proved to be a mass of human hair, was delivered. The upper pole of the mass extended up into the esophagus about two inches and the lower pole rested against the pylorus. (See Fig. 2.)

The stomach was carefully sponged out. No ulcerations were found, mucosa was moderately injected. Stomach incision was closed with three rows of Lembert sutures, No. 1 chromic-gut through mucosa and two rows of silk in muscular and serous coats. Abdominal wound was closed in layers with chromic and silk-worm gut.

Convalescence was uneventful and the patient was discharged well Aug. 7, 1912. She persistenly denied ever having eaten any hair. Patient was last seen Sept. 8, 1913. Health has been excellent since operation, except of late she has "occasional attacks of dyspepsia."

The mass of hair shown in Fig. 2 was found to be composed entirely of long, curly black hairs, loosely woven together, between the meshes of which were many food particles. It weighed before being washed and dried thirty-one ounces. For dimensions see Fig. 2.

The odor from the mass was not unlike that of a very ripe Limburger cheese. The patient's hair was light brown and very thin; but according to Bell[1] the prolonged action of the gastric juice on human hair deepens the shade.

In reviewing the case after operation, the chief error in diagnosis seemed to be in discrediting the patient's gastric history on account

FIG. 2.

Tumor suspended approximately in position it occupied in stomach. Scale showing dimensions. P: Pole resting against pylorus. C: Pole extending up into esophagus.

of her freedom from symptoms while under observation in the hospital. Had a stomach tube been passed, it would doubtless have been obstructed by the mass of hair extending up into the oesophagus. Washing out the stomach, had it been possible, would probably have brought back a few hairs in the wash water as occurred in Hüttenbach's[2] case. X-ray after a bismuth meal would have shown the mass in the stomach. After entrance to the hospital the patient was able to eat anything and was practically free from any gastric disturbance, which led the writer to believe that had there been any symptoms previously, they were of minor importance.

A careful review of the literature on the subject of hair balls was made by Butterworth[3] in 1909 with a brief resumé of the forty-two cases which he found reported. To these cases I am able to add eleven[4] more from the literature, which with my own makes the present number reported fifty-four.

The important conclusions to be drawn from a study of these cases are that:

(1) This is a condition rarely found in men. Forty-eight or over eighty-nine per cent. of the cases were girls or young women, the average age of whom was nineteen and one-half years. This, however, is the age at operation or death. Where the duration of the habit has been carefully inquired into, it has been found to extend over periods varying from two to twenty-two years, which would tend to verify the statement made by many authors that the habit of hair eating is most frequently formed in childhood when the hair is worn loose or in long braids.

(2) Confession of the habit before or after operation, was obtained in less than half of the cases. Therefore, a denial of having eaten hair as in my case is of very little importance.

(3) The prevalent idea that foreign bodies in the gastro-intestinal canal are found only in the insane is erroneous. But six or eleven per cent. of the entire number were mentally deficient or insane.

(4) Nausea or vomiting, though mentioned in but twenty-eight of the cases, probably occurs more frequently, as gastric symptoms are less pronounced, when the patients are kept at rest. Hematemesis, which is considered an important symptom by English writers, is of rare occurrence. In only three, or five per cent., of the reported cases was it observed. Doubtless, this is due to the fact that the masses of hair caused ulceration in but seven cases.

(5) In thirty-nine of the cases a tumor was reported to have been found which was situated in the epigastrium in eighteen patients, in other regions of the abdomen in eleven cases, and the location is not mentioned in ten. These masses are sausage-shaped, very firm, smooth and freely movable.

(6) Of the diagnoses suggested, the spleen seems to be the most frequent offender, being reported in eight cases, malignant tumor in five cases, floating kidney in four cases. Omental tumor, tubercular infiltration, twin pregnancy, hydatid, gumma and cyst of the pancreas are the rarer diagnoses.

(7) The masses of hair vary in size with the duration of the habit and the amount that has been passed in the stool. The largest reported by Mermet D'Hautville[5] weighed six pounds, the smallest two and one-quarter ounces, Thorburn's reported by Pell-Ilderton[6].

Prognosis apparently is uninfluenced by the size of the tumor, the mortality being as high in the cases where large masses are found as in those where only a few ounces had been ingested.

(8) Regarding treatment of these cases, little need be said. Statistics, especially of the earlier cases, prove conclusively the futility of expect-

ant methods. Of the twenty-two cases treated without operation, nineteen died, a mortality of eighty-six per cent. Three vomited masses of hair or passed hair in the stools and recovered.

Twenty-eight patients were operated upon with two deaths, a mortality of seven per cent. In the two fatal cases, the masses of hair had passed into the small intestine and caused obstruction. In four of the cases treatment and result are not mentioned.

THE WORKMEN'S COMPENSATION LAW AND THE PHYSICIAN.*

BY HON. JAMES B. CARROLL,

Chairman, Massachusetts Industrial Accident Board.

As the Workmen's Compensation law has worked out, it is quite evident that the provision which provides for "reasonable medical and hospital bills" for two weeks is unsatisfactory from many points of view. This waiting period of two weeks was originally intended to stop malingering, and fraudulent claims for disability. But it has been shown to the Industrial Accident Board in many ways that when there is a real disability, it is a great hardship for the injured employee to have to wait two weeks before his compensation begins, and this has already brought great suffering to the families of many injured workmen.

In addition to this, it is also manifest that in many cases the two weeks medical attention, which is all that can be legally claimed, is not sufficient in all cases. Only injuries of minor character can be cured in two weeks, and when men are seriously injured and require the attention of a nurse and a doctor more than two weeks, the law is entirely inadequate to fit such cases. In many cases it is quite conceivable that the injured workman might receive compensation at the maximum of $10.00 a week, and still not receive enough to pay his doctor's bill, and that this law, which was intended to relieve the families of workmen injured in industry, would operate to bear down very hard upon them.

But in all these cases, if the medical profession and the public generally will realize the importance of the question, we hope to be able to present the defects of the law to the Legislature in such a manner as to bring relief.

The original medical problems arising under the Act have been at least partially solved by the selection of a committee of seven representative physicians, who from a patriotic desire to benefit the industrial classes primarily benefited by the Act, and to place the medical profession in a proper attitude towards it, have untiringly and unselfishly spent a large amount of time in working out this matter.

That medical matters relating to the Act, under consideration by the Medical Advisory Committee, have been finally settled, cannot, however, be claimed. The desire for dividends, at whatever cost, on the part of certain insurance corporations, and the fact that there are undoubtedly some physicians who are greedy to take advantage of the Act, in order to get fees which they otherwise could not hope to obtain, will probably continue to make trouble. But, happily, the road has been cleared towards an understanding, which we hope will prove satisfactory all around.

When the Act was passed there was no doubt that a majority of the physicians of the State felt the Act was an unwarranted infringement of their rights, and at the meeting of the physicians at the State House, with the Industrial Accident Board, the hostility on the part of the majority of the physicians was only thinly veiled, only to end up with a better understanding all around, and a more charitable appreciation by the physicians that the Industrial Accident Board understood the rights and obligations of the profession.

At this meeting, and in its subsequent actions, the Industrial Accident Board has tried to show that it considers only the best interests of the physicians, and that in the long run, any solution of this matter, which does not satisfy the honest physician who is ready to deal squarely with this subject, cannot be a satisfactory one.

Contract Physicians. When it can be shown, as in one city, that the work formerly done by four or more physicians and paid for at the rate of $5,000 a year, is turned over to one physician, at the rate of $1,200 a year, the contract system, as a whole, cannot justly be defended. Even if it can be shown that the contract system of treating injured employees may work out satisfactorily in rare cases, as a rule it is bound to create trouble. The injured workmen will not, in the majority of cases, receive as satisfactory or skilful treatment, and even the principal object sought by the insurance company favoring the contract system, to wit: The reduction of the cost of medical services, will be a failure, because in the end things of this kind which are cheap, are likely to prove more costly.

Benefits. The medical profession was benefited by the Workmen's Compensation Act in many ways. From the standpoint of money, it

* Read before the Worcester District Medical Society, Sept. 10, 1913.

can be shown that the doctors will get more for services to injured people than was paid out for all kinds of claims, under the former Employers' Liability Act.

But the money in this matter is the least important consideration. Workmen's compensation is only the beginning of a chain of laws to insure workmen against accidents, disease, and ultimately, perhaps old age, and even unemployment.

It is easy to conceive with the progress of these laws, unless properly safeguarded, they may result in the practical enslavement of the medical profession to a bureaucracy created by legislative act. The recent history of certain European countries will bear this out. The Industrial Accident Board has foreseen the possibility in such laws, and this is the reason why such extreme care has been taken that the initial steps in planning procedure shall be along lines approved by the profession generally.

In criticizing the inevitable mistakes of the Board, or of the Medical Advisory Committee of seven, chosen by the medical men themselves, doctors should not forget that the Board and this Committee have always kept in view the ideal of the future of the medical profession who, when things work out as planned, will be left free from the bureaucratic trammels and retain all the rights of which, in the progress of social laws in European countries, in large measure they have already been deprived.

Fees. It seems to the Industrial Accident Board, and to the medical men who have been assisting them in trying to solve the medical problems of this work, that it will be absolutely necessary shortly to agree that the medical fee table shall be put on an industrial basis, and once the principle that industrial accidents shall be classed on an industrial basis, different from the fees in private practice, is established, the whole question of fees will gradually be settled.

Hospitals. In regard to patients who are treated in hospitals, the present law is full of contradictions, and there are many questions to be decided. The injured workman taken to his home is entitled, by virtue of the agreement which the Board has worked out with the insurance companies, to send for his own doctor, but is not entitled to any reimbursement for his board or care. If he goes to a hospital, in ordinary cases the doctor is not entitled to any payment for his services, but board and care are paid for by the insurance company. Many of the hospitals in Massachusetts are charging the insurance companies for the board and care of injured workmen, an amount less than it actually costs them for food.

The Industrial Accident Board is now arranging a conference with hospital superintendents, at which conference charges for hospital services to injured workmen shall be determined, and also the rights of the staff physicians to charge fees to injured employees.

In addition to this, an attempt will be made to define the proper procedure in regard to making employees who are injured, private patients. And it is to be hoped that this conference will result in some kind of an agreement as to the principles of justice which are governing these matters.

THE PASSING OF PARANOIA.*

BY JOHN B. MACDONALD, M.D., HATHORNE, MASS.,

Assistant Superintendent, Danvers State Hospital.

IN the Kraepelin sense paranoia may be regarded not as a disease process but a variety of psychical mal-development showing itself in a morbidly perverted reaction to the problems and affairs of life. Or, to use the words of Meyer, "it is the fulfilment of a fate of peculiar make-up." The disease-picture, if we may apply the term to a condition which is but the expression of an anomaly dependent upon evolutional forces, limits the application of the name true paranoia to a type of individuals perhaps more commonly met outside than inside the walls of institutions. Adhering strictly to Kraepelin's conception we would expect them, for the most part, to be able to adjust themselves after a fashion to their environment, without serious conflict, though often perilously near it.

Briefly stated, as I understand them, the characteristics of true paranoia are delusions representing an unfolding and elaboration of thought processes normal to the make-up of the individual, distinguished by a perverted but clear logic, contact with reality, and originating from actual occurrences; a chronic, incurable course, unyielding faith in, though not necessarily fixity of, the delusions; absence of intellectual impairment and perfect retention of the integrity of the personality.

Upon this hypothesis the task of classifying the true paranoiacs among the insane in institutions is beset with extreme difficulties and perplexities. To determine with any assurance of correctness a diagnosis of this kind in the early stages of a psychosis, one needs not only a clear insight into the nature of this abnormality of mental make-up, a knowledge of the changed opinions on the problem, the variety and number of which indicate they are but stages on the road to a more complete understanding of the subject, but also hindsight and foresight beyond the ordinary endowment of mortals. In determining the existence and value of a peculiar trend arising from make-up as a factor, and in prejudging and fortelling the absence of intellectual impairment and the retention of the integrity of the personality in advance of the prolonged and chronic paranoiac career, the prac-

* Read at a meeting of the New England Society of Psychiatry September, 1913. Danvers State Hospital Contributions, No. 45.

tice of psychiatry becomes a decidedly more intricate and delicate business than the toughest sort of theorizing.

The wealth of material available for study in the case records of the Danvers State Hospital, and the method of case-indexing carried on there for years, offer a fine opportunity for checking up end-results in just such cases as these in the diagnosis of which terminal conditions play so important a part. For the purposes of this meeting we have made a somewhat hurried study of cases diagnosed paranoia and entered as such upon our index-cards. The series undergoing this review comprises all cases so classified since the year 1884, a period sufficiently long in most cases for the detection of deterioration, or developmental symptoms not in accord with Kraepelin's definition. The result of this review by present-day standards of classification is anything but encouraging to one ambitious of attaining to that degree of skill in psychiatric diagnostics involving the power of prophecy. From another point of view it is interesting when considered in relation to the different conceptions of paranoia prevailing at different periods, the incidence of cases for a certain series of years varying according to the trend of psychiatric thought of the time, and marking off quite distinctly the stages of development of our present-day notion of paranoia.

In the twenty-nine years under review the number of admissions primarily classified as cases of paranoia was 51. In the first 15 years of the period we find only three cases, admitted one, each, in the years 1884, 1888, and 1899. The following four years, 1900 to 1903 inclusive, are remarkable by reason of the great increase of cases under this classification, the number comprising 37 or 72.5% of the total for the twenty-nine years. This increased incidence corresponds fairly exactly with the period when the Kraft-Ebbing conception of paranoia was orthodox doctrine. Hallucinations formed an important part in the disease-picture of this time, and mental deterioration, while not considered an integral part of the pathological process was not at all uncommon, the prognosis in this respect being uncertain, depending upon what was considered the accidental development of intercurrent diseases, mania, melancholia, etc., to which it would seem this class of cases was regarded as particularly susceptible.

The influence of the Kraepelin school is seen in the markedly diminished incidence since 1904, —a total of 11 cases for the years 1904 to 1909 inclusive, and the latter year marks the last appearance on our records of a case under this classification.

Of the total 51 cases originally placed in this group, the later histories of 35 show the development of symptoms, or a termination, inconsistent with the primary diagnosis. Of the remaining 16 cases five were under observation for periods not exceeding one year, and four not exceeding two years. In these cases the lack of an adequate after-history following their removal from the hospital renders it expedient to consider them apart as cases where clinical judgment must be suspended for lack of evidence as to their final condition.

We have thus a clear margin of error of 68.6% in the original classification, and ruling out cases not sufficiently long under observation the number of "possibles" determined is reduced to 7 or 13.7% of the total originally classified as cases of paranoia.

In the re-classification of the 35 cases showing the development of symptoms or a termination inconsistent with the paranoia concept, evidence of deterioration was found in 30 cases, or 85% of the number. Of these, probable dementia praecoxes and paranoid conditions comprised the majority. Five cases of the group recovered, one being an acute paranoic condition, two manic-depressive and two alcoholics.

Hallucinations formed a part of the disease-picture in all but three cases of this group. Two of these three presented conditions of beginning apathy and deterioration at admission and the previous history as respecting hallucinosis was inconclusive. In only one of the whole group could it be said with any degree of certainty that hallucinations were non-existant at any stage of the psychosis.

On the other hand in the total of seven "possible" cases hallucinations were definitely determined in only one case. Even here the question of the existence of hallucinations, and the diagnosis, may be open to doubt, the patient being a person of criminalistic tendencies who excused his acts in this connection on the ground that he was driven to them by the promptings of a devil which resided within him and urged him on by audible commands when the opportunity of gain by breaking, entering and stealing was favorable. Strong ideas of reference and illusional misinterpretations gave a pseudo-hallucinatory coloring to the picture in another of these cases.

Summing up our findings by this review of case histories, attention is directed to the relationship between the incidence of cases and the stages of development of our present-day conception of paranoia; the large margin of errors in the classification of early years when the question of prognosis and the study of life histories formed an insignificant or unimportant factor in diagnosis, the rapid decrease in number of cases on record coincident with the acceptance of Kraepelin's idea of absence of intellectual impairment as an essential condition of the picture down to the more recent years when the psychiatric trend seems to have caused "the passing of true paranoia" from the list of the common psychoses. Of equal interest are the findings in relation to hallucinosis, the prevalence of this symptom at some stage of the psychoses in those cases with a mistaken classification of paranoia, and its practical absence in those where the original diagnosis was sustained.

Clinical Department.

REPORT OF A CASE OF BRACHIAL NEURITIS DUE TO PERIOSTITIS OF RIB.

BY R. W. FRENCH, M.D., FALL RIVER, MASS.

THE following case seems interesting because of its rarity and the fact that the condition escaped unrecognized for many years.

The patient, a woman of forty, single, a native of Canada, presented herself at the Highland Hospital, Fall River, for treatment. Her family history and past history were both good. Her present trouble began fifteen years ago and has consisted solely of pain in the third finger of the left hand. It was of very gradual onset, soon became persistent and steadily increased in severity. There was no history of injury nor was there any reason to suspect that her occupation, a dressmaker, contributed to the cause.

For five years she had not worn a glove on the affected hand, inasmuch as contact of the finger tip with any object caused acute pain, as did also gently tapping the end of the finger. Motion of the finger, however, caused no added discomfort.

For the past three years it had been severe enough to keep her awake unless she took aspirin. At first five grains were sufficient, but at the time that she entered the hospital, it required fifteen grains to control the pain so that she could obtain sleep. She was never awakened by the pain.

Various local treatments and internal medications had been tried, and section of the digital branches of the median nerve along the sides of the finger had been proposed.

Local examination was negative, except for acute pain which was caused by tapping the finger tip. In the routine physical examination, however, a small, hard, fixed mass was found just above the left clavicle. It was not tender, but pressure on it increased markedly the pain in the finger. Physical examination was otherwise not remarkable. X-ray examination excluded the possibility of a cervical rib and showed a faint outline of the mass, apparently connected to the superior surface of the first rib.

At operation an incision was made over the mass and dissection carried down to the brachial plexus, one trunk of which was found resting upon an indurated nodule, 2 c.m. in diameter, involving the first rib. The nerve trunk was retracted and the nodule together with a portion of the rib, 3.5 c.m. long, was resected. Subsequent examination of this specimen showed a periostitis. Her convalescence was rapid and uneventful.

She reports now, a year following the operation, that she has had no recurrence of the pain in her finger, and feels perfectly well.

—The secretary of the Michigan State Board of Health has informed the health officer of Benton Harbor that the state has no provision for the care of lepers and cannot, therefore, assume responsibility for Jacob Goldstein. There is no state institution to which Goldstein can be admitted.

Medical Progress.

PROGRESS IN GYNECOLOGY.

BY STEPHEN RUSHMORE, M.D., BOSTON.

FASCIA TRANSPLANTATION.

FREE fascia transplantation in plastic operations is a procedure which has proved of value in a number of applications. Ach[1] has employed it successfully in fixation of the rectum and of the kidney.

In the treatment of floating kidney the steps of the operation are as follows: A vertical incision is made over the edge of the sacro-lumbalis eight to ten centimeters long, exposing the kidney. The necessary displacement is easy. A longitudinal incision is made on the posterior surface of the kidney through the capsula fibrosa, followed by a similar incision on the anterior surface. The capsule is then freed from one incision to the other over the convexity of the kidney by blunt dissection. A strip of fascia from the fascia lata, six centimeters wide and twenty centimeters long, is then drawn under the fibrous capsule from one incision to the other, and the two incisions are closed, perforating the strip of fascia with the closing sutures. The kidney is then restored to its place and the two projecting flaps of fascia are attached respectively to the deep and superficial layers of the lumbo-dorsal fascia. Ach has employed this method in ten cases; all gave anatomical cures, nine symptomatic. The tenth case was a hysterical individaul, who was improved, however.

Ach's experience with rectopexy by this method is limited to one case, but the result was satisfactory after nine months, rather a short time to claim a cure. The method is ingenious and worthy of note, for while the principles of plastic operations may be few and fixed, the practice must be adapted to the individual case, as perhaps in no other department of surgery.

A transverse abdominal incision was made, with considerable elevation of the pelvis. Strong traction on the pelvic colon exposed the cul-de-sac. A wide incision was made around the rectum, freeing that organ down close to the sphincter, especially anteriorly. A strip of fascia lata was then taken, eight centimeters wide and twenty-five centimeters long. Of this one end was split to make two flaps which were attached low in the pelvis. One of these flaps was passed almost circularly around the rectum, to which it was attached by numerous sutures. The other flap was passed low down between the bowel and the vagina and sutured by its free border to each organ. In order to avoid adhesions, the upper end was passed upward, external to the peritoneum, which was dissected free, over the right ureter and through the right broad ligament. Drawing it up to lift the

vagina and rectum as far as possible, it was sutured laterally to Cooper's ligament, and its free end was sutured to the muscle of the abdominal wall. The result immediately and after nine months was good, in spite of the condition of the pelvic floor, which had not been operated on otherwise.

Although free fascia transplantation to close a vesico-vaginal fistula was first suggested by Koenig, there appeared no report of its use until the case of Schmid was published.[2] Schmid employed it in the third operation to close a vesico-vaginal fistula, which occurred after a radical operation for carcinoma of the cervix. The two persistent openings were small, close together, and about in the median line, with considerable scar tissue on both sides. After the usual denudation, the bladder mucous membrane was closed transversely. A rectangular piece of fascia lata, three centimeters by two, was then sutured between the bladder and the vaginal mucous membrane, attaching it by four cat-gut sutures under as much tension as possible. The vaginal mucous membrane was then closed as well as possible, making lateral incisions to loosen the tissues. A retention catheter was left in the bladder until the eleventh day. The wounds healed, giving no trouble with bladder or thigh. The method suggests itself as applicable to those cases of small fistula in which the first operation fails, and as the operation of choice, from the first, in all large fistulas.

ESSENTIAL UTERINE BLEEDING.

In spite of numerous studies and reports of many cases, there is as yet no unanimity of opinion among gynecologists as to the so-called "essential uterine bleedings."[3] "Sclerotic changes" in the blood vessels are often referred to as a cause, but these are due to a physiological process and are not to be confounded with true arteriosclerosis. The old view set forth by Ruge and Veit, and accepted for years, was that endometritis is an important cause of uterine bleeding, for the cases were cured by curettage and microscopical examination showed a hyperplastic condition of the endometrium. But the large number of cases which were not relieved by curettage, or in which no hyperplasia was found, or in which no bleeding occurred, even though hyperplasia of the endometrium was present, suggested the probability of the views expressed by Hitschmann and Adler and by others. Recently renewed interest has stimulated a large number of studies of the subject, the results of which have modified the prevailing opinion, so that now the view is that in the great majority of menorrhagias and metrorrhagias endometritis is not an etiological factor.

The hypothesis of a local hemophilia or of a disturbance of relationship between the glands of internal secretion, has no clinical nor anatomical basis. Since normal menstruation is dependent on the presence of the ovary, there arose naturally the theory that disturbances of menstruation were due to disturbances of ovarian function. But no generally accepted basis for this connection has been found. If a series of cases of ovarian tumors is studied and compared with normal cases with reference to the question of bleeding, there is found no anatomical basis for the correlation of bleeding to ovarian changes. In general, as is well known, the hemorrhages occur most frequently about the time of the menopause, when the function of the ovaries is rapidly diminishing. If hypersecretion or hyperfunction of the ovary were the cause of uterine bleedings it is extremely improbable that it would occur about the menopause rather than at the time of greatest sexual activity.

Hirsch claims that while the chief factor in uterine bleeding is defective contraction of the uterine muscle, another important factor is involved. This is a hyperemia which affects not only the uterus but the whole pelvic area. The condition of the uterine musculature which renders its strength inadequate for the blood content of the uterus, that is, insufficient to withstand the blood pressure and drive the blood on through the pelvic circulation to the heart, may be spoken of as uterine insufficiency.

Against this theory of uterine insufficiency is the fact that typical changes in the endometrium or myometrium are not found. But such typical findings are not necessary for proof, for the weakness is not absolute, but relative, there is simply a disproportion. In the presence of a typical anatomical picture there would be no bleeding if no hyperemia occurred. Even in almost complete degeneration of the uterus into connective tissue, as in the senile state, hemorrhages do not necessarily occur. Only slight bleedings occur if hyperemia is absent, as in anemia, chlorosis, general adiposity, chronic intoxication and all wasting diseases.

Hirsch describes normal menstruation as follows: There is hyperemia of the uterus and other pelvic organs due to an ovarian hormone, leading to diapedesis and bleeding. Before it becomes considerable, uterine contractions set in and the bleeding often diminishes or even ceases for hours, the uterine contractions being perceptible to the patient as "drawings" in the abdominal or sacral region. Insufficiency of uterine contraction or of the uterine muscle occurs if there is a maladjustment between the blood content of the uterus and the strength of the uterine musculature. This means simply that hemorrhages are due to functional disturbances of the uterine muscle based in the majority of cases on anatomical changes in the uterine wall. Such changes, however, may be entirely lacking. Uterine insufficiency is thus exactly analogous to uterine atony found in the so-called chronic metritis in which the hemorrhage is due to functional disturbances and not to anatomical impairment. In the case of bleeding from the subinvoluted uterus, we find very well developed musculature, but it is unable to control the

marked overfilling of the puerperal uterus with blood.

In the study of the hemorrhages in virgins, anatomical investigations are not possible, as the patients do not die, or if death does occur, hemophilia cannot be excluded. But even from the hypoplastic uterus hemorrhage does not arise if the general condition of the body is so poor that the usual stimulus at menstruation is insufficient to cause hyperemia. If, however, hyperemia occurs and the uterine muscle is too weak to resist the pressure of blood by contracting, hemorrhage takes place.

Schickele's view that changes in the metabolism of the ovary affect the coagulability of the blood in the uterus, Hirsch does not accept. Therapeutic tests indicate that no such hypothesis is needed, for the usual means of checking hemorrhage are such that in no way can they affect the ovarian metabolism. These measures are in fact only variations in the means of stimulation of uterine contractions.

Among drugs ergot is the most important in producing contractions, and it should be injected directly into the uterine muscle. The effect is astonishing and not exactly comparable to subcutaneous or oral administration. Often one injection is sufficient, the contraction lasting for several hours (2-3-6-7). Occasionally the injection has to be repeated on several days.

The treatment is indicated in nearly all cases of bleeding from uterine insufficiency, and in the past three years Hirsch has employed it in about two hundred cases. There are certain contraindications, as in the case of young girls in whom local treatment is not advisable. In most myomata there is danger of necrosis and infection, but small, interstitial myomata present no contraindication. In all acute inflammatory conditions of the uterus and of the appendages ergot is to be avoided, and especially in malignant disease and in extra-uterine pregnancy. In postpartum atony with hemorrhage the injection into the tissue of the cervix is far safer than packing the uterus or applying the Momberg belt.

The technic is as follows: The portio is exposed and disinfected. It is then grasped with a hook or bullet forceps and an injection is made with a sterile syringe deeply into the muscle of the portio, introducing the needle parallel with the surface of that organ, and using one-fourth, one-half or one gram of ergot preparation. If the injection is made as directed, large uterine vessels are avoided, and thus faintness, nausea and vomiting, which occur if injection into vessels takes place. Following the injection the patient should lie quiet for a while.

CARE OF THE WOUNDS IN THE RADICAL OPERATION FOR CANCER OF THE CERVIX.

The general line of procedure in the radical operation for cancer of the cervix would seem to be for the present fairly well established. The results, however, are not satisfactory for the mortality is high in spite of the marked improvement which has been evident in the more recent reports as familiarity with the operation has increased. A large proportion of the deaths have been due to infection, arising in the pelvic or abdominal wounds and causing fatal peritonitis. Bumm[4] presents the method used in his clinic to obviate this danger. It is worthy of careful consideration on account of its evidently wise provisions and also because of the reduced mortality, which in a series of one hundred cases reached only six per cent. With the exception of the care of the wounds the procedure is the same as that previously employed, and the operability was practically unchanged (65%).

This gratifying result, which Bumm says a few years ago he would have regarded as impossible of attainment for the radical operation, he attributes chiefly to the treatment of the pelvic wound, namely, the complete rejection of the use of drains and the complete closing in of the peritoneal cavity. Infection is sometimes unavoidable, but, by the complete closure of the peritoneum the danger of infecting its cavity is markedly reduced. The objections to drain are well known, the chief one being that they do not drain. Gauze as a pack to check oozing which there is not time to check by sutures, is useful but dangerous.

The important points in Bumm's technic may be noted briefly. Operation on febrile or subfebrile patients is avoided, if possible, but not refused, as the danger of post-operative complication is greatly increased if infection is already present. The carcinoma is curetted and cut away and thoroughly cauterized with the thermo-cautery, which latter process will sometimes considerably reduce the size of the mass, through contraction due to drying out by the heat. The vulva and vagina are disinfected with an alcohol-sublimate solution and the vagina is treated with a 10% solution of silver nitrate until the mucous membrane is of a gray-white color. Finally a gauze tampon wet with the silver nitrate solution is left in the vagina until just before it is cut across from above.

During the abdominal operation protection against infection is careful. The wound surfaces of the abdominal wall are covered with gauze tacked in place by sutures. The high Trendelenburg position is employed, with large gauze compresses to wall off the general cavity, which compresses are not changed until they are removed at the end of the operation. The instruments are frequently boiled, the gloves washed in running water, and finally the escape of carcinomatous material on cutting into the vagina, is prevented by a special clamp.

The thorough vaginal disinfection has perhaps shown its value in eleven cases, in which the carcinoma thinned by curette and cautery was torn into or through, during the abdominal operation, with apparently no bad results. Formerly this accident was regarded as of ominous import.

Of importance equal to the disinfection is the complete hemostasis, with needle and suture, and avoidance of injury of neighboring organs. As a rule the areolar and adipose tissue from the bifurcation of the iliac artery almost to Poupart's ligament and down to the stump of the uterine artery is removed with the glands. Suturing of the iliac artery or vein, if injured, is preferred to ligation, and has been entirely adequate in Bumm's few cases of this accident. The ureter is less frequently injured than formerly and Bumm prefers ligation if it should for any reason be cut across too high for implantation into the bladder.

The treatment of the pelvic wound is, after complete hemostasis, to suture the peritoneum and of bladder and rectum to the vagina. This closes in two large raw areas. Then the raw areas laterally are closed in by running sutures, or, if there is tension by interrupted sutures. Care should be taken to see that no dead spaces are left. There is then run a catgut suture from one infundibulo-pelvic ligament to the other, low down in the pelvis, approximating the peritoneum of the anterior and posterior walls just above the first line of suture. Thus the general cavity is closed off from the vaginal vault.

Bumm mentions numerous other minor but valuable points in the technic, for a description of which the original article must be consulted.

SARCOMA AND THE X-RAY TREATMENT OF MYOMATA.

When the conservative treatment of myomata was introduced, the question of operation on account of fear of sarcoma was raised for the first time. It has of late again come into prominence chiefly through the opponents of the x-ray treatment who have pictured the situation in dark colors. They say that every patient with sarcoma is lost without operation and nearly every patient operated on is saved. But before these dicta can be accepted and before the matter can be decided, several questions have to be answered, according to Miller.[5]

1. Are sarcomata as frequent among myomata as the opponents of the x-ray treatment claim?
2. Are sarcomata so difficult to diagnose?
3. Are practically all sarcoma patients saved by operation?
4. Is it not possible that sarcomata may be healed by x-ray or at least controlled and restrained?

To these questions just such answers as we would wish are not at hand, because the number of cases operated on far exceeds the number of cases treated with the x-ray, and the time of observation for the latter group of cases is too short. But a study of the literature will throw light on some of the points under discussion.

The percentage of frequency of sarcoma in cases of myoma is about two, judging from statistics based on nearly eighteen thousand myoma cases. The results of radical operation in myoma cases show a collective mortality of between four and five per cent., while the results of operation in sarcoma of the uterus show at best not more than 25% of cures.

In regard to diagnosis there is little to be made out in the early stage of the disease, for then differential diagnosis of malignancy is practically impossible. So that on this point the literature may be studied to advantage to see from the histories what cases would have been treated by x-ray and thus the diagnosis have been overlooked. From the cases subjected to this test, there were first excluded all frank cases of sarcoma of the cervix, chorionepithelioma and carcino-sarcoma as they do not come into the group considered, and for the same reason cases under twenty-five years of age. One hundred and eighty cases were found reported in the literature and were considered in some detail. The histories were subjected to the judgment of Professor Koenig who applied the tests now in force at the Freiburg clinic.

Of one hundred and eighty cases, 55, or 30.5% were considered suitable for x-ray, 64.4% not suitable, and in regard to 5% a decision could not be made on account of the defective history. The actual error of diagnosis was found from the various tables which are given to have been 43.2% per cent. Now since sarcoma occurs in about 2% of the myoma cases, the error of diagnosis would be for all cases approximately .8%. This then represents the mortality which could be directly traced to sarcoma developing in myoma cases subjected to x-ray treatment. Recalling then the collective mortality of myoma operations of from 4 to 5%, and the percentage of cures of sarcoma operated on as only 25, it is seen that there is good reason for stating emphatically that the fear of sarcoma should not be a determining factor in deciding between x-ray and operative treatment for myomata. The decision should be made on other grounds.

SUGAR IN THE TREATMENT OF INFECTIONS

The principles underlying the use of sugar in dealing with bacterial infections Kuhn has published previously [6, 7]. They would seem to deserve more attention than they have received. In recent articles[8, 9] Kuhn briefly reviews the essential parts of what he has written before, and applies the principles to gynecology and obstetrics. The acidity of the vaginal secretion is connected with its bactericidal action, for as the acidity is diminished this action decreases. The acidity is due chiefly to the presence of lactic acid, but the anti-bacterial action is due chiefly, not to the lactic acid, but to biological processes, of which lactic acid is an end product. For bacteria produce acid, that is to say cause fermentation, or produce alkali, that is to say, cause putrefaction, according to the kind of food they have. It is the presence of some carbohydrate

substance in the vaginal secretion which makes possible the production of the lactic acid. If sugar, then, is introduced into the vagina, it will increase carbohydrate decomposition, decrease proteid decomposition, as most bacteria show a preference for the carbohydrate, and by its presence change over the pathogenic bacteria, temporarily, at least, into harmless saprophytes. Sugar has also a distinct antiseptic action in strong solutions and rapidly causes bacterial degeneration in weak solutions.

In obstetrical cases, a prophylactic use of sugar solutions might be made, increasing the resistance of the birth canal to infection, by physiological processes. During the puerperium, in any case in which intrauterine douches are indicated, the introduction of a sterilized solution of sugar, 25 to 50% in strength, would perhaps prevent uterine infection. Through osmotic action a free flow of lymph would be set up into the cavity of the uterus; by this the products of bacterial action would be neutralized, and the metabolism of any accessible germs would be so changed that they would no longer produce harmful toxins, but simply cause fermentation. Kuhn does not report results as shown by the treatment of cases, but the basis of treatment is well founded. Clinical results in several conditions are reported by others.

Prager-Heinrich[10] calls attention to the excellent results which have been obtained in the treatment of leucorrhea by means of "xerase," which consists chiefly of sugar and yeast. The treatment with a dry powder has given better results than douches or moist tampons. The cervix is exposed and the vagina is dried as thoroughly as possible. The powder may be introduced by a "powder blower," which is rather time consuming, or by means of a long handled small spoon, or just "shaken in." The powder is kept in place by a tampon. The next day "camomile tea douches" are given, but any mild astringent might be employed. Any form of leucorrhea can be benefited and even acute gonorrheal infection is amenable to a course of these applications. The per cent. of failures (all kinds of cases) as given by Prager-Heinrich is small, 7%.

There is an especially troublesome form of discharge which can be relieved by the use of sugar, namely, that from inoperable cancer of the cervix. Here Berczeller[11] has employed powdered sugar, introduced through a tubular speculum. The vagina is half filled with sugar, which is kept in place by a tampon of iodoform gauze. The treatment may be repeated daily or less frequently as occasion demands up to once a week. The foul odor and the discharge quickly disappear, the bleeding diminishes and the patient's general condition improves.

Reports of Societies.

THE AMERICAN NEUROLOGICAL ASSOCIATION.

THIRTY-NINTH ANNUAL MEETING, HELD AT WASHINGTON, D.C.

MAY 5—7, 1913.

THE PRESIDENT, DR. PEARCE BAILEY, NEW YORK, IN THE CHAIR.

PRESIDENT'S ADDRESS.

In all organic life there exists two principles for action, viz., desire and fear; desire showing itself as a tendency on the part of the individual to acquire for himself what is beneficial, and fear a tendency to avoid, by whatever means possible, what is harmful. There soon become associated with these two motives, the emotions of pleasure and pain. As evolution proceeds, these two motives become enormously elaborated to form instincts, and through all the instincts, one or both of them can be found. With the development of the intelligence, the instincts become very much checked and modified, so that desire shows a constructive purpose and fear becomes sunk in the unconscious, showing itself chiefly as prudence. Human personality is a combination of the instincts with fear and desire back of them, modified by the checks of the intelligence, but the fundamental motives can always be detected, and man, however much his primal characteristics may be hidden by the teachings of his intelligence, nevertheless remains essentially an egotistic individual. This can be shown by analysis, in his ordinary actions, and becomes very evident under any circumstances which accompany an unhinging, temporary or permanent, of his intellect. Thus, under the stress of violent emotions, of fatigue, of physical disease and especially of mental disease, the teachings of the intelligence are more or less lost sight of, and a man reverts or regresses to earlier types of behavior. Under these circumstances, he shows various phases of the evolutionary stages through which the race has passed.

PRESENT STATUS OF NEOSALVARSAN IN THE TREATMENT OF PARASYPHILIS OF THE NERVOUS SYSTEM.

DR. EDWARD D. FISHER, New York: Since the finding of the spirochetes in the brain and cerebrospinal fluid in general paresis and tabes the term parasyphilis must be discontinued. All diseases of the nervous system due to syphilis are due to the same active agent which is the cause of the pathological changes both in cerebrospinal syphilis and in the more chronic manifestations formerly classed under the head of parasyphilis. The discovery of the spirochetes gives us a rational basis for the use

of neosalvarsan. The question arises: What is the relative efficiency of this remedy in the later manifestations of syphilis of the nervous system, i.e., in tabes and general paresis? In my experience the hopes raised by Prof. Ehrlich's discovery have not been fully realized and can not be. We have only to consider the pathological changes in these diseases to understand the reason why. We have, however, with the Wassermann reaction test a rational plan of treatment in the use of neosalvarsan and mercury with iodides. As we find the Wassermann test negative we can stop our medication and resume it as it becomes again positive. It is certainly rational to remove the active agent of disease, as we can by the use of neosalvarsan, and thus prevent further extension of the disease. In the light of our present knowledge, we are in a position to make an early diagnosis, and the importance of beginning treatment early is emphasized. The importance of being conservative in our claims for this most valuable remedy should be emphasized as it must be many years before we can know whether its early employment, *i.e.*, at the time of the initial lesion, prevents the later manifestations of syphilis of the nervous system.

DISCUSSION.

DR. JOSEPH COLLINS, New York: I find myself accord with Dr. Fisher in regard to the necessity of once now and forevermore dispensing with the terms parasyphilis and metasyphilis. I am not sure that we all recognize a fact which seems to be a fact, namely, that when face to face with tabes and general paresis and what is known under the term of meningeal syphilis, we are not dealing with a nervous disease, but dealing with the disease syphilis. I understood Dr. Fisher to say that the spirochetes are found in the cerebrospinal fluid. I supposed that they had never been found in the cerebrospinal fluid.

DR. PHILIP COOMBS KNAPP, Boston: The clinical and pathological distinction thus far justify the division into ordinary syphilis and parasyphilis and this a convenient distinction which I think might still be held. In regard to the use of neosalvarsan and salvarsan my experience has been that there is a good deal still in Ehrlich's original claim that in syphilis of the nervous system the results are not so likely to be beneficial as in the early stages of syphilis manifesting itself in other organs of the body. Experience both with neosalvarsan and salvarsan in syphilis of the nervous system has not, on the whole, led me to believe that we have gotten so much more than we had in the use of mercury and iodine. In the last two months I have been trying the intraneural method and thus far the benefits of the method seem to be uncertain and possibly not of sufficient value to warrant the increase of danger that accompanies the use of that method.

REPORT OF A CASE OF JUVENILE TABES.

DR. C. EUGENE RIGGS, St. Paul: A boy seven and a half years old, no luetic history in either parent, no symptoms of hereditary syphilis began to have gastric crises when about ten months old; they now occur every three months. Marked ataxic gait, muscular weakness, knee and Achilles jerks absent. Positive Wassermann in blood serum and spinal fluid; no lymphocytosis, no globulin excess.

DISCUSSION.

DR. PHILIP COOMBS KNAPP, Boston: Cases of juvenile tabes are so rare that it seems permissable to speak of a case now in my wards, which, altho not confirmed by autopsy, seems to me probably a case of juvenile tabes. A girl of 16 of whom nothing can be learned in regard to her family history. At the age of five she was run over and her head injured, suffering several scalp wounds and being unconscious for a day. After that there was no trouble at all until the age of eleven, when her sight began to fail. At the age of twelve she had lost vision completely. Someone examining the eyes found optic atrophy of the so-called traumatic origin. There had been a history for one or two years of typical tabetic pains, sharp, shooting pains of brief duration. On examination there was some perception of light and well-marked primary atrophy of both disks, no indications of any keratitis, no radiating scars about the lips. The two central upper incisors were peculiar in that they were somewhat broad, but not characteristic of Hutchinson's. The knee jerks were absent on one side, obtained only by reinforcement on the other. There is marked Wassermann in the blood and the cerebrospinal fluid and globulin reaction, but no increased lymphocytosis.

DR. H. M. THOMAS, Baltimore. A boy of seven was sent to the surgical department of Johns Hopkins with the diagnosis of tumor, probably of the cerebellum. I was asked to see him in consultation. The child had been extremely bright up to the fifth year, when he had begun to deteriorate, and then it was thought that he had an injury. His deterioration took the form of being unable to speak as well as he had before; he had been loquacious; he became noisy and fretful and hard to manage and his walk became so unsteady that he could hardly get about. On examination he showed no sign of hereditary syphilis. He had no choked disk, his walk was distinctly cerebellar, his pupils were distinctly unequal; they did not react to light and his reflexes were exaggerated. The boy's blood gave the positive Wassermann reaction, and the diagnosis of cerebral syphilis was made. He was given two doses of neosalvarsan and changed markedly. He became quieter, his walk became steadier and he left the hospital having done pretty well. However, on getting home he became extremely quiet and in a week he was brought back in an absolutely different condition. At that time he was speechless, his walk was perhaps a little less ataxic, still he made no attempt to walk. The physical signs were the same. We did a lumbar puncture. He had a cell count of 33, positive globulin and positive Wassermann and a Wassermann in his serum was also positive. The case then seemed to be one of juvenile general paresis, and, as it was the only case, we did not venture to make that diagnosis, yet we have been extremely interested.

TWO CASES OF REMOVAL OF EXTRA-DURAL TUMOR OF THE SPINAL CORD.

DR. PHILIP COOMBS KNAPP, Boston: Tumors of the spinal cord are rare. In 3617 autopsies at the Boston City Hospital a tumor was found only four times, but the spinal cord was not always spared.

In 1294 patients in the neurological service a tumor was diagnosticated 10 times. In 11 cases operation has been performed in six cases with fatal results, in four with some improvement, so that the patient could get about on crutches, and in the fifth with marked improvement followed by a return of symptoms and a second operation. Two of these cases were reported:—

CASE 1. Woman, 40, married, nullipara. Menopause at 37. Considerable alcohol. Entered hospital May 20, 1912. For six months or more had had pain between the shoulders, shooting into arms and worse on motion. For three or four months the pain had been growing worse; for six weeks the legs had been numb and for two weeks paretic. Micturition was difficult, and the urine at times had to be drawn. Sexual desire unimpaired. Some rigidity of dorsal spine. Legs paretic and spastic. Knee jerks exaggerated, double Babinski. Sensibility diminished from level of ensiform cartilage downward. Unable to pass urine, which contained a trace of albumen and some pus. Wassermann and Noguchi in blood, positive. The cerebrospinal fluid was clear, 20 lymphocytes to a cubic millimetre; globulin reaction absent. Wassermann and Noguchi negative. Somewhat vague shadow in upper dorsal region. The paresis increased to complete paralysis, the spasticity was much greater. Salvarsan and mercury did not benefit her. July 30 laminectomy by Dr. E. H. Nichols. Two small masses were removed from external posterior surface of dura at level of sixth dorsal spine. Made a good surgical recovery. She gradually improved, regaining control of her bladder, being able to stand alone and walk with crutches, and having normal sensibility. She was still somewhat spastic and had exaggerated reflexes. She is still on crutches and in the hospital for chronic diseases.

CASE 2. Woman, 33, married, four children. Entered hospital July 30, 1912. Three years before, in the sixth month of her fourth pregnancy, began to have pain in right loin, buttock and leg. After delivery legs grew weak. Pain subsequently appeared in left leg. Loss of sexual desire, micturition and defecation imperative, occasionally incontinence. Gradual increase in weakness of legs. When first seen was unable to stand or walk without support. Sensation diminished below a line two inches below umbilicus. Tender over lower dorsal vertebrae. Some spasticity. Wassermann and Noguchi negative. Lymphocytes 20 to a cubic millimeter. Laminectomy August 16, by Dr. J. A. Hubbard. Small growth, apparently fatty, removed from posterior external surface of dura at level of eleventh dorsal spine. Dura opened, arachnoid bulged, no pulsation. Considerable fluid drained from arachnoid. Some fever and bedsore, but otherwise she made a good surgical recovery. Gradual recovery of motion and sensation. Able to stand and take a few steps on Sept. 7. Toward the end of October walked without crutches, and later improved so that she could walk half a mile, dance, and travel in the trolley cars alone. Early in January, 1913, she took cold, and her symptoms gradually returned, so that early in February she returned to the hospital in much the same condition as in the previous July, but the hyperesthesia extended to two inches above the umbilicus. There was a good deal of pain in the back and the legs were weak and spastic. March 15 the wound was re-opened by Dr. Hubbard, and the spinous process above was removed. No adhesions were found, but the cord was tense and did not pulsate. The dura was opened and much cerebro-spinal fluid escaped. She made a good recovery and was discharged April 21. There was then a very slight hyperesthesia with some allocheiria in the right leg. The right leg was somewhat hypertonic, but she had good strength in both legs and could walk with crutches or with very slight support. The operations that had been done in Boston, 14 of which had been already reported, had been collected, and showed the following results: Tumor removed 8, 6 improved, 2 died; tumor partly removed 7, 3 improved, 4 died; tumor found, not removed 4, 2 improved, 2 died; lesion found, not tumor 6, 3 improved, 3 died; nothing found 6, 3 improved, 2 died, 1 result uncertain. Shersburg collected 119 operations; of these 49 were benefited, 42 died.

A PECULIAR AND UNDESCRIBED DISEASE OF THE NERVES OF THE CAUDA EQUINA.

DRS. FOSTER KENNEDY AND CHARLES A. ELSBERG, New York: During the last five years, in a large number of spinal operations, 84 of which were performed by one of the writers, they have met with five cases alike in their histories, their clinical findings, and in the peculiar swelling and discoloration of the roots of the cauda equina, that they have been led to class them together in the belief that they form a definite clinical and pathological entity. Pain was present in the back of the thighs and legs in all of the patients; atrophy of the anterior muscles with loss of the power of dorsal flexion of the foot was present in 4; the objective sensory changes consisted of loss in the sacral and lowest lumbar nerves. The disorganization of the functions of the bladder and rectum was complete in four patients. The abdominal reflexes were regularly present, while the ankle jerks were lost in four; the knee jerks became lost coincident with the upward progress of the disease. The conditions found at operation were mainly a swelling and reddish-blue discoloration of many or all of the roots of the cauda equina. A thorough search of the literature failed to reveal any proven case like those described. A few cases have been reported in which a clinical diagnosis of neuritis of the cauda equina was made and the condition believed to be syphilitic, but in none of these was the diagnosis verified by operation or autopsy. A very similar disease has been described in the horse, and in these animals the postmortem examination revealed a condition very like that found in the patients operated upon and reported in the paper. The Wassermann test both in the blood and cerebrospinal fluid was negative in all of the cases, therefore the condition is not luetic; nor were there any signs of a meningeal lesion.

GIANT TUMORS OF THE CONUS AND CAUDA EQUINA.

DRS. JOSEPH COLLINS AND CHARLES A. ELSBERG, New York: The patient begins to complain of pain and stiffness in the back, extending down the posterior aspect of one and then of the other thigh. The pain is intermittent at first, later it is continuous. After the expiration of one year or more, the symptoms become worse, one or double drop foot appear, the lower limbs become weaker and stiffer, knee and ankle jerks disappear. Then follow difficulties in the functions of the bladder and rectum,

irregular sensory loss, rigidity of the lumbar vertebral column, tenderness of the lumbar spine. Peroneal palsies are regularly found with electrical changes. The patients are often suspected of tabes, and have usually been treated for long periods for sciatica. The important features of the clinical histories were the following. A history of one or more years' duration; pain in the small of the back, sooner or later extending down one and then the other extremity; stiffness of the back in the lumbar region; increasing weakness and stiffness of the lower extremities, with loss of power of dorsal flexion of the foot; slight disturbances of the bladder and rectum. The important features of the clinical examination were the following: Rigidity of the lumbar vertebral column; weakness and stiffness of the lower limbs; paralysis of the peroneal groups of muscles and sometimes of the tibialis anticus group; dropped foot on one or both sides; absence of knee and ankle jerks; tenderness of the lower lumbar spines; irregular and unsymmetrical sensory disturbances; lumbar puncture usually negative, no fluid obtained, Wassermann test and x-ray negative. The typical findings at operation consisted of a large reddish-brown, not vascular, tumor within the dura, which filled up the entire lower part of the spinal canal, surrounded the roots of the cauda equina and extended upward on the conus, with which it was not closely connected. The growth is not intimately connected with the inner surface of the dura, and can be easily freed, from after which the inner surface of the dura is found to be smooth and glistening. The growths are well encapsulated above, but are closely connected with the nerve roots below. The peculiar features of the tumors are: their large size; the late appearance of bladder and rectal disturbances; the relatively small amount of sensory loss in spite of the fact that the tumors fill up the entire lower part of the spinal canal; the benign course of the disease, without tendency to perforate the dura. Operative interference should be done in two stages by the "extrusion" method. If the cases are recognized early, radical removal of the growths should be possible.

The above three papers were discussed jointly.

DR. ARCHIBALD CHURCH, Chicago: I am reminded by Dr. Knapp's paper of an experience of comparatively recent date, which, while it might not be edifying, might be interesting; that was, the recurrence of three tumors followed by three successful operations on the same patient. The first tumor made its appearance four years ago. At the end of a year the patient was entirely paraplegic. Dr. Patrick saw the case in consultation. Dr. Murphy operated. A tumor was removed from the cervical region. She made an uneventful recovery and in the course of six months recovered. At the end of two years she began to have the same symptoms of spinal tumor and within six months had developed the same symptoms. A second operation found another growth in connection with the pia about an inch lower than the first tumor. Whether this was a recurrence of the first growth was not known. It was supposed to be essentially an independent neoplasm. For nine months she had comparative freedom. Two weeks ago she came back to Chicago for recurrence. Early last week a third operation was done and a third tumor removed. So there was one on the right, one on the front and one on the left. I have had two cases of cauda equina. Some eight years ago a surgical friend had the typical manifestations of caudal lesion. This endotheliomatous growth filled the entire neural cavity and was supposed to be so intimately related to the cord that no attempt was made to remove it. The man perished from kidney trouble. About three years ago I saw a young boy with terrible pains in the legs who had been treated as hysteria. After many months of observation he showed a little area of sensory loss corresponding to the cauda and upon this comparatively slight symptom, although the bladder was not materially affected, an operation was done and an infiltrating endotheliomatous neoplasm extending from the middle of the lumbar spine to the lower end of the sacral canal was uncovered. It was not thought feasible to remove it and safest to let the case take its course. The operation wound has remained perfectly solid. The symptoms have not increased, but a tremendous growth has invaded the abdomen so that he looks like a six-months' pregnancy. Apparently the pressure has been relieved from the caudal region so that further neural symptoms are inhibited and the growth has gone in the anterior direction. This large caudal involvement may be more frequent than we suppose.

DR. W. M. LESZYNSKY, New York: In regard to the difficulty of diagnosis in tumors of the cauda equina and inflammation of the roots, the mere fact that one can obtain no cerebrospinal fluid should lead one to make the differential diagnosis between the two conditions.

DR. WILLIAM G. SPILLER, Philadelphia: This subject of the root neuritis confined to the lower portion of the cord is one of great interest. One can't help wondering whether in this case there was a meningitis of a certain degree, possibly of a considerable degree, and whether the root changes were not part of this meningitis. Dr. Elsberg said that the cord showed nothing by the naked eye. There may be marked meningitis which is not to be detected by the naked eye at all. Tumors vary very greatly as to whether they are in the upper part of the cord or in the lower. In the upper they are more of the type of fibroma and endothelioma, well defined tumors that may be readily removed in most cases. In the lower part of the cord they are very much more malignant, infiltrating, liable to be of greater size and offering much more unfavorable conditions for removal. In one case of inoperable tumor I got Dr. Martin to cut the antero-lateral columns to remove the pain. It was very successful. The patient lived two years after that operation. He died a few months ago, with an enormous tumor filling a large part of the abdomen.

DR. JOSEPH COLLINS, New York: It seems useless, so far as the patient's restoration to a degree of health and usefulness is concerned, to operate on these caudal tumors as they are now being operated upon, my experience being that it does not give them any considerable degree of life and does not restore them to any degree of health. The significance of this fact is that we must diagnosticate these cases earlier than we do now. If we rely upon the presence or absence of the cerebrospinal fluid in a case that has the symptoms of caudal tumor in making the differential diagnosis, we will go wrong very frequently. I would make a plea for operation on caudal tumors in every instance at the time when suspicion enters our mind that these are present, and, second, for operation in tumors of the conus five, six, eight, ten years before the time they are now operated on.

A CONTRIBUTION TO THE PATHOLOGY OF MYASTHENIA GRAVIS.

DR. SIDNEY KUH AND DR. MORRIS BRAUDE, Chicago: Ours was a typical case of myasthenia gravis in a physician fifty years of age, of a duration of about five years. Examination of nervous system was made with the Weigert myelin sheath stain and Pal's modification of the same, Mallory's chloride of iron hematoxylin, Ford-Robertson's toluidin blue, thionin, Nissl's methylene blue, toluidin blue counterstained with erythrosin, uranium carmin, Van Gieson's stain, Weigert's fibrin stain and the same author's stain for elastic fibres were used on about 400 sections. Small areas of vascular sclerosis, recent (agonal?) hemorrhages, increase in glia tissue, corpora amylacea were found in the spinal cord. In the cervical region there was an aberrant bundle of fibres. In the higher levels of the cord capillary polymorphonuclear thrombi and chromatolysic and pigmentary changes were seen in the nerve cells. The relative intensity of these latter findings remained approximately constant, *i.e.* where the thrombi were numerous the changes in the nerve cells were greater. The same applied to medulla and corpora quadrigemina. In the cortex there was but little of these changes to be seen; more in the optic thalami. The muscles showed nothing that had not previously been described. There was no trace of the thymus found.

BILATERAL OCULOMOTORIOUS PALSY FROM SOFTENING IN EACH OCULOMOTORIUS NUCLEUS.

DR. WILLIAM G. SPILLER, Philadelphia: Bilateral oculomotorius palsy developing in an apoplectic attack, syphilitic in origin, implicating every muscle supplied by the eculomotorius in each eye, resulting from bilateral softening as two separate lesions confined to the nuclei of these nerves; without implication of other cranial nerves except the opticus, and without other symptoms except preceding mental disturbance, convulsions and some change in the patellar reflexes and succeeding extension of each big toe from plantar irritation are the chief features in the case reported in this paper. The author discusses the several symptom-complexes resulting from vascular occlusions he has studied, viz. the occlusions of the posterior inferior cerebellar artery, of the uppermost portion of the anterior spinal and adjoining portion of the vertebral arteries, of the cervical anterior median spinal artery, of the vessels supplying the inner segment of each lenticular nucleus, and (in the case reported in this paper) of occlusion of the vessels to the oculomotorious nuclei. In the last mentioned condition there are symmetrical softening and paralysis of all branches of the oculomotorius, although the paralysis may not be complete in all the muscles enervated by the nerve; there are also involuntary incoördinate movements and great rigidity with unconsciousness at the onset of the attack.

THE PERIMETRIC DEVIATIONS ACCOMPANYING PITUITARY LESIONS.

DR. HARVEY CUSHING, Boston: In a series of 104 examples of pituitary diseases, the greater number accompanied by manifestations of tumor, due either to an enlargement of the hypophysis itself or to a superimposed lesion, changes in the fields of vision have been present in a large proportion of the cases.

Few physicians at the present time venture to make a diagnosis of an hypophysial lesion in the absence of a bitemporal hemianopsia; and it has been our experience that the majority of the neurologists and ophthalmologists through whose hands these patients have passed, have hesitated to make such a diagnosis—although there were obvious deviations from the normal in the perimetric outlines—for the reason that these deviations did not show the characteristic bitemporal defect with a more or less definitely vertical meridian separating blind from seeing fields.

As a matter of fact, in a considerable number of these cases the field defect has been an homonymous one, for when the enlarging gland bursts through its dural capsule it may extend into the interpeduncular space to one side of the chiasm rather than in a median posterior position.

The opportunity has been given in this series of cases, not only in many instances to follow the progressive changes in the visual fields as the defect advances, but also to follow the steps by which the normal peripheries become restored after a transsphenoidal operation, when partial removal of the growth has afforded relief from pressure. These experiences have shown that in the majority of instances the defect advances in very characteristic fashion, usually beginning in the upper and outer temporal field and affecting color vision before vision for form.

These minor changes are as typical of a retrochiasmal lesion as is the full-blown text-book picture of complete bitemporal hemianopsia. Furthermore, the defect rarely advances with equal steps in the two eyes, and consequently for each individual eye it proves to be a matter of clinical convenience to divide the advancing process into stages, as follows:

Stage 1 shows merely a notch, often quadrantal, in the upper temporal field for color, though there may be in addition some slanting off of the form field. This is due to the fact that the ventral crossed fasciculus is affected by the pressure at an earlier stage than is the dorsal crossed fasciculus, the transmission of color impulses suffering earlier than the transmission of form impulses.

Stage 2. In this stage a beginning quadrantal constriction in the form field follows upon the quadrantal defect for colors.

Stage 3. Here color vision is more or less completely lost in the entire temporal field, the form constriction remaining practically quadrantal, with beginning encroachment upon the lower temporal field.

Stage 4. In this stage hemianopsia is complete for form and colors, the macula still being spared by the otherwise practically vertical meridian.

Stage 5. Hemianopsia remains complete for form and color, the macula now being included in the vertical meridian, there being in this stage often an actual complete macular blindness for colors.

Stage 6. Macular vision is lost for form as well as colors and the nasal field begins to shrink from the vertical meridian.

Stage 7. Color vision is entirely lost and a patch of vision for large objects remains, usually in the lower nasal quadrant.

Stage 8. Blindness.

The least affected eye progresses in the meantime along the same route; for it cannot be emphasized too strongly that the process rarely advances with equal steps in the two eyes. Indeed, commonly

enough, one eye may be completely blind, whereas the other may show a condition in Stage 1, or indeed with no observable change whatsoever.

Even after Stage 8, with blindness, has been reached some vision may be regained by operative measures; which goes to show that the disturbance is brought about, not only by an anatomical destruction of the fibres through a process of degeneration, but also by a physiological block to the transmission of impulses superimposed on the actual atrophic changes.

Though the prospect of a return of vision, therefore, is not utterly hopeless, even when blindness has supervened, it is, nevertheless, of great importance for us to recognize these evidences of chiasmal pressure in their early stages.

Pituitary disease, as I must continue to emphasize, is a common malady, heretofore largely overlooked. One serious complication of the disorder is a so-called primary optic atrophy; and this is in many respects the most obvious of the neighborhood symptoms and one for which surgical measures are as definitely indicated as when dyspnea is produced by pressure against the trachea in cases of goitrous enlargement of the thyroid gland.

(To be continued.)

Book Reviews.

Therapy at the Bonn Univeristy Clinics. Edited by PROF. DR. RUDOLF FINKELNBURG. Bonn: A. Marcus and E. Weber. 1914.

This German volume presents a purely practical therapeutic compendium from the medical, psychiatric, neurologic, surgical, ophthalmic, otologic, rhinologic, gynecologic, and dermatologic clinics at Bonn. The attempt is made by the editor to coördinate the methods of the various departments on the basis of etiologic treatment. Emphasis is also laid on negative therapeutic results and on special technic. Each section is by the chief of the respective clinic. Much of interest will be found by students and practitioners in every division of this book, which represents the cumulated experience of years in the professional life of leaders in the several departments of medicine.

The Principles and Practice of Medical Hydrology. By R. FORTESCUE FOX, M.D. (Lond.); F. R. Met. Soc. London: Hodder and Stoughton and Henry Frowde. University of London Press. 1913.

In the sub-title of this book, medical hydrology is defined as "the science of treatment by waters and baths." It is the work of a recognized English expert, issued in the series of London Medical Publications. The author aims "to discuss the various actions of water and baths on the body, without more detail than may enable medical men to apply for themselves these methods of treatment. The first section of the book describes the physiology of bathing, with a note on children's baths and school baths. The second section considers hydrotherapy, with a note on hydrotherapeutic institutions. The third deals with medicinal springs and baths, and the fourth with indications for hydrologic treatment. The volume is an interesting and convenient manual for those concerned with this important but often neglected department of therapeusis.

Medical and Sanitary Inspection of Schools. By S. W. NEWMAYER, A.B., M.D. Illustrated with 71 Engravings and 14 full-page plates. Philadelphia and New York: Lea and Febiger. 1913.

This volume, by the chief of the division of child hygiene of the Philadelphia Bureau of Health, is intended as a guide "for the health officer, the physician, the nurse, and the teacher" in the physical examination of school children. There are also chapters on the sanitation of school buildings and on methods of preventing epidemics of contagion in schools. The introduction describes the development of medical inspection of schools in the United States, a procedure first established in Germany, tentatively introduced in Boston a score of years ago, and now recognized universally as a measure of undisputed importance for the present and future public welfare. This work on the subject should prove an excellent practical manual for all concerned with the hygienic and sanitary administration of schools.

Text-Book of Anatomy and Physiology for Nurses. By AMY E. POPE. With 135 illustrations. New York and London: G. P. Putnam's Sons. The Knickerbocker Press. 1913.

"The object of this work is to provide a textbook containing more physiology than the books on anatomy and physiology hitherto provided for nurses." It is unfortunately true that physiology often gets scant attention or is altogether neglected in the instruction of nurses in training-schools, yet it is really more important than detailed knowledge of form. Interest in structure should not be allowed to overweigh interest in function; for the product is really the object of ultimate importance, not the machine. Hence the author's purpose in this book is especially laudable, and she has fulfilled it exceptionally well. The text is clearly written and well arranged, the illustrations are abundant and helpful, a number of them being in colors. There is an extensive and serviceable glossary, and a useful appended table of food values compiled by Miss Alice C. Keith. The book should find immediate recognition and prove a great aid to pupil nurses and to their teachers.

THE BOSTON
Medical and Surgical Journal

THURSDAY, JANUARY 1, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: $5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

MEDICAL LEGISLATION. THE PRACTICE OF DENTISTRY IN MASSACHUSETTS.

THE importance of medical legislation and of legislative measures affecting not only the public health but the practice of medicine, can hardly be overestimated in any community. Naturally such legislation, to be sound and equitable, should rest fundamentally on enlightened professional opinion. Unfortunately this opinion is often imperfectly formed, vague, or based on inadequate information. To crystallize the professional judgment of physicians on topics of legislative concern not only should be of advantage to them, but should be a definite aid to legislators desirous to further the public welfare by acting on the concerted counsel and opinion of medical men.

During the early part of the year, therefore, the JOURNAL will, as heretofore, devote especial editorial attention not only to legislative measures pending before the General Court, but to the discussion of desirable measures not yet shaped into actual form. It will aim in every case to state the facts clearly and impartially, to indicate the opinion of experts on the subject in hand, and to point out the probable effects, advantageous and disadvantageous, of the passage of the law or bill under consideration.

Of the measures early to come before the present session of the legislature, one of the most important is that affecting the practice of dentistry in Massachusetts. This measure was before the General Court in 1913, and was defeated by the opposition of those who did not approve the opportunity which the bill afforded for the employment of dental assistants to clean teeth, when such assistants were not themselves trained dentists. The present bill has been revised in such a way as apparently to make such employment free from any possibility of abuse, and at the same time productive of much good to the community. Its provisions are in substance as follows:—

"Section 1. There shall be a Board of Dental Examiners consisting of five persons, each of whom shall be a legal resident of this Commonwealth, a reputable dentist and a graduate of a reputable dental college, with an actual practice in dentistry in this Commonwealth for the five years next preceding his appointment. Said board shall examine candidates for registration in dentistry. The present members of the Board of Registration in Dentistry shall constitute this board and shall serve out the respective terms for which they have been appointed. No member of the board shall be a member of the faculty or board of trustees of any institution engaged in educating dentists.

"The governor, with the advice and consent of the council, shall have power to remove from office any member of said board for continual neglect of duty required by this act, or for incompetency or dishonorable conduct.

"Said board shall have full power to make and shall publish necessary rules and regulations for the proper fulfilment of its duties under this act. It shall choose one of its members chairman and one secretary and shall hold at least two regular meetings each year in Boston. A majority of the board shall constitute a quorum for the transaction of business. Said board shall keep a full record of its proceedings and a full registry of all persons certified as denists by said board, which shall be public records and open to inspection.

"A transcript of any of the entries in such record, certified by the secretary, shall be competent evidence of the facts therein stated. The board shall have the power to summon witnesses and to administer oaths and hear testimony in all matters pertaining to the duties imposed upon it by law. On or before the first day of January in each year, said board shall render to the Governor a full and accurate account of its proceedings, receipts and disbursements during the year immediately preceding."

The remainder of this section specifies the salaries, fees, time and place of meeting of members of the board.

"Section 2. After the passage of this act, any person over twenty-one years of age and of good moral character, who is a graduate of an accredited high school or presents proof of equivalent training and has received a diploma from the faculty of a reputable dental college,

as defined in this act, shall upon fulfilment of requirements for applicants as hereinafter specified, be entitled to examination by the Board of Dental Examiners. If found competent, he shall be registered by said board and shall receive a certificate of such registration signed by the secretary of the board, which shall be prima facie evidence of the right of the holder to practice dentistry in this Commonwealth. In proof of this right the certificate or a duplicate shall be kept in his office and shall be shown to any member or agent of the board on application.

A dental college shall be considered reputable which possesses the following qualifications:

"First: It shall be chartered and authorized by its charter to confer degrees of doctor of dental medicine or doctor of dental surgery.

"Second: It shall deliver a full course of lectures and instruction by a competent faculty and corps of instructors, said course to consist of not less than three separate academic years of not less than thirty-two weeks each of six days for each week, and shall require each matriculate to be a graduate of an accredited high school or to present proof of equivalent training."

The remainder of this section describes the details of application for examination:

"Section 3. No person not a registered dentist shall directly or indirectly practice dentistry in the Commonwealth of Massachusetts, except as provided in this act.

"It shall be unlawful for any person or persons to operate any dental office under any name or corporation name other than the name of the person or persons therein actually engaged in the practice of dentistry.

"Any person shall be said to be practicing dentistry within the meaning of this act who shall use the word or letters 'dentist,' 'D. M. D.', 'D. D. S.,' or any other letter or title in connection with his name, which in any way represents him as engaged in the practice of dentistry, or who shall for a fee, salary or other reward paid or to be paid, either to himself or to any other person, perform dental operations of any kind, diagnose or treat diseases or lesions of the human teeth or jaws, replace lost teeth by artificial ones, or attempt to correct or diagnose malposition thereof, or who shall advertise or permit it to be done by sign, card, circular, hand bill, newspaper or otherwise, that he will perform any or all of the aforesaid operations.

"But nothing in this act shall prevent any person from cleaning teeth under the direction of a registered dentist. The cleaning of teeth shall include only the removal of all stains and deposits from the exposed surfaces of the teeth and polishing said surfaces. Nothing in this act shall apply to treatment by a registered physician not practicing dentistry as a specialty, nor prevent a registered dentist of another state or his assistant from operating at a public clinic under the auspices of a duly organized and reputable dental college or association, nor prevent a student of a reputable dental college, incorporated under the laws of this Commonwealth, from performing operations as part of the regular college course.

"A registered dentist shall have the same right to prescribe or buy drugs or medicine for use in the conduct of his practice as the registered physician of this Commonwealth."

It will be seen that the object of previous contention lies in this third section of the bill, which makes it possible for an assistant or nurse, not a dentist, to be employed in "cleaning teeth under the direction of a registered dentist." This provision is intended especially for the benefit of the public in school dental clinics, where the cleaning of teeth is a large part of the work to be done and is an agent of great prophylactic value in anticipating dental caries. Obviously it is impossible that this should all be done by dentists. It must, therefore, either be left undone, or must be done by such competent assistants as those for which this act makes express provision. The possibility of violation of the spirit of the law seems obviated by its restrictions:

"Section 4. The Board of Dental Examiners, after giving due notice and hearing, may revoke or suspend the certificate of any dentist:

"First: For felony or misdemeanor involving moral turpitude, in which case a record of conviction or finding of guilt or a certified copy thereof, certified by the clerk of the court or the judge in whose court the conviction or finding of guilt is had, shall be conclusive evidence.

"Second: For gross ignorance or inefficiency in his profession or for obtaining a certificate of registration or any fee, by fraud or misrepresentation, or for the advertisement of dental practice, treatment or devices in which untruthful or improper statements are made, or for habitual intemperance or gross immorality, or for wilful violation of the provisions of this act.

"Said board by a majority vote may reissue a revoked certificate after one year from date of revocation.

"A dentist aggrieved by the action of the board in the revocation or suspension of his certificate, may apply to the Supreme Judicial Court in the county in which he resides, or in the County of Suffolk, for a writ of mandamus requiring them to revoke their decision if the same is found on hearing to have been erroneous."

Sections 5, 6, and 7 respectively provide the penalty for unregistered practice, repeal pre-

vious conflicting legislation, and fix the date at which the act shall take effect.

This measure, as it now stands, is approved by a majority of members of the Massachusetts Dental Society and, from a socio-political standpoint, by the Massachusetts Civic League. The latter organization has stated the following as some of the reasons why it advocates the passage of this bill:

"1. The Massachusetts dental law is behind those in most of the states. Other New England states have modern laws enacted in recent years. The aim of the proposed law is to bring Massachusetts up to date.

"2. This law will get under many of our difficulties. From ninety to ninety-eight per cent. of our school children have dental defects. Eighty per cent. of these defects could be prevented by proper cleaning of the teeth. Under the Massachusetts law no one but a registered dentist may clean teeth. There are not enough dentists to handle the school children alone. Cleaning teeth is a simple matter. The proposed law provides that it may be done by anyone under the supervision of a dentist, and that a dentist who abuses his privileges shall have his certificate taken from him. In short, under the new law we can prevent an enormous amount of dental decay and other defects.

"3. Bad teeth have an important part in the break-down of physical and nervous conditions. They are also directly responsible for the spread of contagious diseases. Cases are known where decayed teeth have carried disease germs for many months after the patient recovered, others catching the disease. Decayed teeth offer one of the best breeding grounds for germs.

"4. There is some tendency to the belief that this is not a social problem. To all who believe that it is better to take care of broken-down individuals there is perhaps no answer. To those who believe that it is the function of society to keep people on their feet there seems to be a good case to present. It is because of the constructive elements in the proposition that the Massachusetts Civic League has taken it up."

These reasons seem cogent.

The opponents of the proposed measure object to its provision for dental assistants on the ground that the latter may usurp the functions of dentists and interfere with the work of legitimate practitioners. It does not seem that with the careful restrictions now imposed by the revised measure this objection is any longer valid.

The present bill has been carefully drafted by a body of dentists after conference with all persons and parties concerned. We feel that it is a desirable and progressive piece of legislation, and recommend its passage into law.

THE MENTALLY DEFECTIVE IMMIGRANT VIEWED FROM A SOCIOLOGICAL STANDPOINT.

IN a recent number of *The American Magazine*, Arnold L. Gesell, now a teacher in Yale University, presents us with a eugenic study of "The Village of a Thousand Souls." The village contains 220 families and may be accepted as typical. In the course of his very interesting and illuminating article Professor Gesell states:

"We can appraise and classify the families of our Village of a Thousand Souls with reference to certain large characteristics. We can do this to some success without the assistance of a psychological laboratory because, after all, life itself is the most comprehensive test and the token of the character of these villagers. The school, the street, the places of work and business, the yards, the gardens and the playgrounds have been the public stage upon which the lives of the inhabitants of The Village of a Thousand Souls have been manifested."

In discussing the definition of feeble-mindedness Professor Gesell approaches the subject from the medical, pedagogical, psychological and sociological standpoints. From the medical standpoint feeble-mindedness may be said to be a permanent arrest of development of the nervous system, especially of the brain cortex. From the pedagogical viewpoint a feeble-minded person is one who cannot be taught to read, write or cipher, with any marked advantage to himself or to society. Psychologically, feeble-mindedness means that there is a condition of "permanent, incurable mental retardation limiting the individual to an intelligence less than that of a normal thirteen-year-old child." Viewed from the sociological aspect, Professor Gesell states that feeble-mindedness is a condition of relative mental incompetence, dating from birth or infancy, which makes it impossible for the individual to get along in the world on equal terms with his normal fellows. And it is this last definition which Professor Gesell found most useful for his eugenic survey of "The Village of a Thousand Souls."

A recent article by Dr. Bernard Glueck, of the United States Public Health Service at Ellis Island, deals with the problem of the mentally defective immigrant from the sociological standpoint. He has given us an original, sane paper which is well worth careful reading by all those who are interested not only in the immigrant but in the mentally defective in general.

After first reminding us that what we regard as the normal mind is but "the usual, the common, the everyday mind as we encounter it determining the usual, the common, the everyday conduct and behavior," and after calling our attention to the wide range of normality with its infinite possibilities for variations, Dr. Glueck next considers the definition of feeble-mindedness. He chooses the definition adopted by the British Commission for the Study of the Feeble-Minded. According to this definition the feeble-minded are individuals who on account of incomplete cerebral development are unable to perform their duties as members of society in the position of life to which they were born. This, it will be seen, is a social definition. It takes into account the native qualities and capabilities of the individual, his age, education, opportunities, race, etc. It considers the individual as a biological unit, as a member of the society or the community in which he will take his place.

The various measuring scales of intelligence, such as the Binet-Simon scale and the American modification by Goddard, although of the greatest usefulness in detecting feeble-mindedness, depend upon the comparison of the examined individual's intelligence with a given standard of average normal intelligence, for a certain race, under certain conditions. It gives us an artificial classification of feeble-mindedness, which can only serve to augment but cannot entirely replace the social one. This applies especially to the adult, and more particularly to the immigrant, in whom, in order to arrive at a rational conclusion with respect to the feeble-mindedness of an individual, as judged by the measuring scales, we must first have a definite idea of the average standard with which the results to be obtained are to be compared. It is necessary to know his past life history, his degree of adaptability in life as judged by his past performances, his daily conduct, his ability to earn a living and to lead a normal, law-abiding life. We must know whether he was able to look after himself and whether the normal instincts of man were properly controlled and directed.

In studying the defective immigrant from this standpoint Dr. Glueck endeavored to gain a correct idea of the average normal intelligence of a given race and for this purpose he selected at random fifty individuals of the Polish race, ranging from 18 to 40 years of age, whose outward appearance suggested nothing abnormal, who had never attended school and did not know how to read or write. The tests employed were chiefly performance tests, the element of language being thus eliminated to as great an extent as possible. For the series of tests employed reference should be made to the original article. Dr. Glueck's conclusion is worthy of quoting verbatim: "Here we have fifty individuals who were as near alike in most respects as is possible among human beings. Under circumstances which were as nearly alike as possible, these individuals were given the same thirty-eight problems for solution, and the results of correct answers varied all the way from eighteen to the full thirty-eight."

The lesson is plain: The measuring scales have, up to the present, consisted in an examination of the knowledge or intellect of the individual. We have too often lost sight of the fact that man is a feeling, living, active being, with emotions and instincts. The biologic and sociologic approach to the study of the mind of man is the only rational method of approach. It is fundamental and basic. The psychologic tests cannot entirely replace but must be considered in connection with the life-history of the individual. We believe, with Dr. Glueck, that it is possible to evolve a set of questions which would represent, as nearly as possible, what the average immigrant of a given race should be able to accomplish mentally, if he is to be considered normal.

NATIONAL INSURANCE IN GERMANY.

The first of January marks the culmination of an important struggle in Germany between the medical profession and the insurance societies through which the national sick and benefit insurance is administered. The grievance of the German doctors, as of the British, is that they are not adequately recompensed for panel work, and that free choice of physicians by patients is not allowed. Negotiations between them and the insurance companies were pending throughout the past summer, but were frustrated by representatives of the companies.

Finally on Oct. 26, a representative meeting of physicians, held in Berlin, voted that "on and after Jan. 1, 1914, the insured population of Germany,—Dresden, Hamburg, and Berlin ex-

cepted,—shall not receive treatment through the insurance societies unless the latter meet the demands of the profession or the government sees fit to interfere." Following this action special meetings and conferences of medical societies and insurance agents were held on Nov. 5 in Munich and Baden. The federation of insurance societies, however, refused to comply or to recognize the right of the doctors to organize the profession for the protection of the general practitioner.

On Nov. 12 the Berlin Medical Society, at a special meeting, endorsed the action of the representative meeting of Oct. 26 by the passage of the following resolution:—

"In consideration of the fact that the manner in which the insurance societies desire to regulate the relation between the doctors and the societies under the new State Insurance Order most seriously imperils the freedom and independence of the medical profession, both of which are absolutely necessary for the continued scientific education and for the beneficial activity of the doctors, in the interest both of the patients and themselves, the *Berliner medizinische Gesellschaft* joins whole-heartedly with the German medical profession in its struggle with the managers of the insurance societies."

Thus matters have stood until the present time. If the doctors remain firm and united, they will effectually block the operation of the national insurance law on and after today. Either the companies must yield or the crown will intervene to settle the dispute.

We have not yet the subject of national insurance among the vexing problems of professional life and legislation in our country; but it may come to vex us sooner than we now expect. Meantime the experience of our German and British brethren is full not only of intense interest, but perhaps of profitable precedent.

MEDICAL CERTIFICATION FOR MARRIAGE.

THE reported refusal of members of the Milwaukee Medical Society to issue for three dollars certificates of complete physical examination and fitness for marriage, is evidence of a sensible reaction against the impracticability of enforcing a so-called eugenic marriage law requiring such medical certification of the contracting parties before the issuance of a marriage license. Such an examination as could reasonably be expected for that fee would be worth little for the detection of possibly communicable venereal infections, or of susceptibility to other undesirably transmissible diseases. Moreover, even with the most complete possible physical examination, a conscientious physician must in many cases hesitate to guarantee a man or a woman fit for matrimony. Finally, if the state makes it impossible to procure marriage licenses without medical certificate, the very persons whose procreation is least desirable will take measures to secure the ends of matrimony without license. After all, marriage, in the long run, must, like all other contracts, rest ultimately on the mutual confidence of the contracting parties. A man whose word cannot be trusted that he has not had syphilis or gonorrhea prior to marriage, cannot be trusted not to acquire them after the issuance of his medical certificate.

THE DIAGNOSIS OF HAMLET.

THE interest manifested from time to time in the medical problems afforded by Shakespeare's characters is only another evidence of the intense and vital reality of the personages whom he created. Indeed, in this respect, they equal Napoleon and the monarchs of England in the amount of post-mortem discussion to which they have given rise.

Recently an editorial in *The Medical Press and Circular* has essayed another inferential diagnosis on Hamlet. "Gouty diathesis, ptosis, and auto-intoxication" are held to be the pathologic trilogy which accounts not only for his obesity, cardiac symptoms, and other physical signs, but for his alternate saturnine gloom and hysteric gaiety. It is not long since one of the Freudians settled upon him the universal Oedipus complex. (This, by the way, will doubtless also soon be found in Peter Pan.) Next the endocrinologists will probably "explain" Hamlet, like Napoleon Bonaparte, on the basis of hypopituitarism.

As a matter of fact, Hamlet, whatever his physical organization, had a sane and noble mind; which remains for us as the most nearly perfect portrait that Shakespeare has left of himself.

MEDICAL NOTES.

EDWARD N. GIBBS MEMORIAL PRIZE FUND.—This fund was established by the wife and daughter of the late Edward N. Gibbs, and its income, which amounts to about five hundred dollars, is used in aiding investigators into the cause and treatment of diseases of the kidney. The recipient of the fund is chosen annually. The committee will select the worker for 1914, about the first of February, and requests all persons who desire to work under this fund, to send to the committee of the Edward N. Gibbs Memorial Prize Fund, 17 West 43rd Street, New York City, their application, together with a statement of their fitness to prosecute such investigations, giving the laboratory in which they have studied, and any researches conducted by them, in order that the committee may be guided in the selection of the recipient of the fund for 1914.

AMALGAMATION OF OHIO MEDICAL SCHOOLS.—Report from Ohio on Dec. 24 states that all details have finally been arranged for the projected union of the Starling Medical College with the medical school of Ohio State University.

MANUFACTURE OF MESOTHORIUM IN AMERICA.—It is announced on Dec. 21 that a Philadelphia corporation is to begin the commercial manufacture of mesothorium in this country, from extensive thorium-bearing deposits which it controls in the Carolinas.

TYPHOID FEVER IN WASHINGTON.—Report from Centralia, Wash., on Dec. 19, states that typhoid fever is at present epidemic in that town. On Dec. 15 and 16, 42 new cases of the disease were reported, making a total of 160 since the beginning of the outbreak.

DANGERS OF TRICHINOSIS.—On Dec. 21 the United States Department of Agriculture issued at Washington, D. C., a statement warning the public against the dangers of consuming uncooked pork. It has been found that of all hogs examined by government inspectors 1.41% are infected with trichinosis.

AN ABSTINENT CENTENARIAN.—William E. Tearis, who died in Jersey City, N. J., on Dec. 18, 1913, is said to have been born in 1810 at Huddersfield, England. He migrated to the United States in 1820. It is reported that he ascribed his persistent good health and longevity to his habits of deep breathing, interest in public affairs, and abstinence from alcoholic beverages.

SMALLPOX ON THE OHIO.—Report from Guantanamo on Dec. 18 states that the United States battleship *Ohio* was quarantined at that port on her arrival from the Mediterranean with smallpox aboard. One sailor died of the disease during the voyage, and 11 cases are now under treatment. The source of the infection has not been determined.

EUGENICS IN MILWAUKEE.—Report from Milwaukee, Wis., on Dec. 17, states that the Milwaukee Medical Society has voted that its members shall not issue, at the statutory charge of $3, certificates of complete physical examination and fitness for marriage, as required by the new eugenic marriage law in that state.

BOSTON AND NEW ENGLAND.

HOSPITAL CONCERTS FOR JANUARY.—It is announced the concerts of the Boston Hospital Music Fund for January, 1914, will be given at 2 p. m. as follows:—

Jan. 4—Cambridge Homes for the Aged.
" 11—St. Elizabeth's Hospital, Boston.
" 18—St. Luke's Home for Convalescents, Roxbury.
" 21—Home for Destitute Catholic Children, Boston.
" 25—Boston City Hospital.

HONOR TO A BOSTON SCIENTIST.—It is announced that Dr. Charles Sedgwick Minot, professor of comparative anatomy at the Harvard Medical School, has been recently elected an honorary member of the Anatomical Society of Great Britain and Ireland.

WORK OF RHODE ISLAND HOSPITAL.—The recently published fiftieth annual report of the trustees of the Rhode Island Hospital, at Providence, records the work of that institution for the year ended Sept. 30, 1913. During this period the total number of patients treated in the hospital was 7881; the total attendance in the out-patient departments, 40,414; and 4278 cases were treated in the accident rooms. Thirty-six nurses were graduated from the training school, and 101 autopsies were performed by the pathologist. There was a large pecuniary deficit.

INFECTIOUS DISEASES.—Cases of infectious diseases reported to the Boston Board of Health

for the week ending Dec. 23, 1913: Diphtheria, 42, of which 3 were non-residents; scarlatina, 89, of which 11 were non-residents; typhoid fever, 8; measles, 44; tuberculosis, 56, of which 1 was non-resident. This last item was for the week ending Dec. 20, 1913.

The death-rate of the reported deaths for the week was 19.57.

NEW YORK.

AMENDMENT OF SANITARY CODE.—At a recent meeting the City Board of Health passed a resolution amending the Sanitary Code by adding a new section, to take effect March 1, 1914, and to read: Bichloride of mercury, otherwise known as corrosive sublimate, shall not be held, kept, sold or offered for sale at retail in the dry form, except in colored tablets individually wrapped, the wrapper to have the word *"Poison"* in plain letters conspicuously placed, and dispensed in sealed containers of glass conspicuously labeled with the word *"Poison"* in red letters. This section, it is announced, does not apply to tablets containing one-tenth of a grain of bichloride, or less. The board has also placed trichinosis among the notifiable diseases.

HEALTH EXHIBIT.—On Dec. 17 a permanent health exhibit was opened in the building of the Department of Health, on Centre Street, and on this occasion the principal speaker was the venerable Dr. Stephen Smith, known as the "father of the New York Health Department," who was health commissioner from 1868 to 1875. Commissioner Lederle presided, and others who spoke were Prof. Charles F. Chandler, health commissioner from 1875 to 1883, and Drs. A. Jacobi, H. M. Biggs, and T. Mitchell Prudden. Among the exhibits is a fine model of the Otisville tuberculosis sanatorium.

A WET CLEANER.—The New York Edison Company, against which the Health Department has so long been bringing complaints for maintaining a smoke nuisance, has now, after a course of experimentation lasting three years and involving, it is said, an expenditure of $500,000, succeeded in securing an apparatus, known as a wet cleaner, which removes the objectionable qualities from the smoke from its plants. The smoke is driven at high speed through a large tank of water, and in this is left practically all the material which constituted a nuisance.

WORKMEN'S COMPENSATION LAW.—The workmen's compensation law, which was recently passed by the legislature, fixes rates of compensation the general basis of which is two-thirds of the average rate of wages paid at the time of injury, and each specified disability is to be compensated for by the payment of this average weekly sum for a defined number of weeks. In case of permanent partial disability the aggregate of weekly payments is limited to $3,500, while in case of death the employer is to pay funeral expenses not exceeding $100 and to pay to dependents of the deceased workman, as specified, an amount not more than two-thirds of the weekly wages. This ceases in case of a widow, with re-marriage; when, however, two years' compensation may be paid in a lump sum. In case of children the payment ceases when the age of 18 is reached. The only exception to the employer's liability is when "the injury is occasioned by the wilful intention of the injured employee to bring about the injury or death of himself or another, or where the injury results solely from the intoxication of the injured employee while on duty."

NEW HOSPITAL IN BROOKLYN.—A recent ten-day campaign in Brooklyn to raise $100,000 to erect a hospital for the House of St. Giles the Cripple, a home for crippled children at Garden City, resulted in the securing of $105,000. The movement was under the direction of Dr. B. B. Mosher, surgeon-in-chief to the institution. It is purposed to locate the new hospital in Brooklyn, and when the patients become convalescent they will be transferred to the Garden City home.

INADEQUATE PROVISION FOR FEEBLE-MINDED.—In a report of the committee on idiots and feebleminded of the State Board of Charities it is stated that, while it is estimated that in the state of New York there are not less than 30,000 persons who should be segregated for their own protection and the good of the community, the state, including the minor political divisions, up to the present time has made provision for less than 4,000. With the completion of Letchworth Village and the contemplated extensions at the institutions at Rome and Newark, provision will have been made for the care of approximately 7,000; and the committee urges the expediting of the plans for these.

1. Pearce believes that prophylactic vaccination rests on a sound scientific basis, but curative vaccination has no sound experimental basis. The only logical method is the use of autogenous vaccines. Mixed vaccines commercially prepared are unscientific and non-ethical. Vaccines rarely cure but rather aid by stimulating a languid process of immunization.

2. Wright makes a very sane plea for the more careful and systematic study of the criminal class and the individual criminal with the view to the gradual abolition of the penitentiary and the treatment of the criminal as a diseased individual and not a social malefactor.

5. Huffman, examining 68 specimens of tubal pregnancy found malformation of the tube in 54%. He believes that this evidence, besides the negative findings in regard to any obstruction or inflammation, is sufficient to warrant the establishment of the anomalous-embedding-area theory as the most logical of all explanations for ectopic pregnancy. [E. H. R.]

2. Harmer and Dodd present a series of x-ray photographs which show gastric stasis in cases where the stomach tube had failed to obtain fasting contents. The source of error lies in the fact that the tube does not always accommodate itself to the curves of the stomach wall and its tip may become impinged so that it does not reach the most dependent portion of the organ. The writers point out that failure to recover gastric residuum with the unaided stomach tube cannot be accepted as conclusive evidence of the absence of gastric stasis.

3. Aschoff discusses at length the experiments of many investigators on the subject of thrombosis. Neither endothelial damage nor a direct coagulation

of the blood play any rôle in thrombosis formation. Slowing of the blood stream and alteration of the blood elements themselves, especially the platelets, are the chief factors in the production of both static and toxic thrombosis. In the formation of static thrombi slowing of the blood stream is of prime importance, while for the toxic varieties changes in the blood elements have the dominating influence. Coagulation of fibrin almost inevitably follows thrombosis. First comes the erection of a morphological structure by a process of agglutination. Fibrin ferment is obtained from the agglutinated elements and cements them together by coagulation.

4. Hawley studied the blood pressure in mental cases at the Illinois Psychopathic Institute. In mania, he observed that pressure was always elevated. In stuporous cases it was low, probably because of relaxed blood vessels. In depressed states blood pressure is lower than in manic states, but higher than in stuporous states. In melancholia it is normal unless there is muscular resistance or some other factor to produce a rise.

8. Lamb reports the results of prophylactic inoculation against typhoid fever among nurses and attendants at the Presbyterian Hospital, New York. Of especial interest are his observations on the effect of the vaccine upon menstruation; 53% of the nurses vaccinated showed some type of menstrual disturbance, the type being very variable and more than one occurring occasionally in one person. Allowing for unavoidable errors in deduction, there is a very striking relationship between the vaccine and the menstrual disturbances, and between these disturbances and those seen in typhoid fever. The writer believes that the vaccination of women should be so arranged that the first inoculation will come a few days after a period. The second and third injections can then be given at seven-day intervals, leaving about a week before the succeeding period. A pregnant woman should not be vaccinated unless there is urgent indication for it.

9. Hanglik and Collins report on an elaborate clinico-chemical study of the antiseptic action of hexamethylenamin in body fluids. They find that hexamethylenamin itself is not bactericidal and that its beneficial therapeutic effects depend upon the formaldehyde liberated from it. This liberation depends upon the excess hydrogen ion concentration of the solution above the neutral point. Alkalies prevent and acids facilitate this liberation of formaldehyde in all normal and pathologic body fluids. After administration hexamethylenamin is present, but does not liberate free formaldehyde in blood, cerebrospinal, pleural, pericardial and synovial fluids, vitreous and aqueous humors, and alkaline urine. Formaldehyde is liberated in acid urine and in the acid gastric contents. The administration of monosodium phosphate with hexamethylenamin, by rendering the urine acid, facilitates this liberation. The administration of alkalies with hexamethylenamin is irrational.

7. PARKER, R. *A Simple Splint for Flail Elbow.*

1. Lewis discusses cardiac and renal asthma as seen in many cardio-renal cases and discusses the cause of this phenomenon. Fundamentally he believes it to be due to an increased acidosis of the blood, which he discusses in some detail.

4. Deanesly discusses at some length the diagnosis and treatment of intestinal obstruction. He believes that large numbers of patients die each year from intestinal obstruction of a mechanical nature easily remedied by operation, who have been treated for chronic constipation with drugs, etc. He describes the symptoms, signs, etc., and operative treatment of this condition. [J. B. H.]

THE QUARTERLY JOURNAL OF MEDICINE.

VOL. 7. NO. 25. OCTOBER, 1913.

1. *RITCHIE, W. T. *Further Observations on Auricular Flutter.*
2. *GRAHAM, G., AND POULTON, E. P. *On the Variations in the Excretion of Endogenous Uric Acid Produced by Changes in Diet.*
3. HALL, I. W. *Review. Uricemia and Gout.*
4. *PARKINSON, J., AND ROWLANDS, R. A. *Strychnine in Heart Failure.*
5. *SUTHERLAND, G. A., AND PATERSON, H. *On a Type of Cerebral Mal-development (Forebrain Aphasia).*
6. *WALLIS, R. L. M. *On Sulphemoglobinemia.*

1. By auricular flutter is meant an extremely rapid but rhythmical action of the auricles, as distinguished from auricular fibrillation, in which there is a complete absence of rhythm. Ritchie has observed one case of auricular flutter and complete heart-block for seven and one-half years; the auricular rate varied from 250 to 276 a minute. Lately, however, the auricular rate has fallen to 190, and there has been a change in the electro-cardiagram and the auricular rate has become subject to vagus control, so that Ritchie considers the present state of the heart to be one of auricular tachysystole rather than true flutter. Ritchie also describes in detail the findings in the heart of a fatal case of flutter, in which lesions of the sino-auricular node were the most conspicuous. Lastly, he reports a case in which there were transitions between fibrillation, flutter, and an intermediate state. Under the influence of digitalis, as often happens, the condition changed to one of permanent fibrillation. This change has an analogy in the change from flutter to fibrillation noted experimentally when the vagus is stimulated during faradization of the dog's heart.

2. Graham and Poulton found a fall in the endogenous uric acid output under three conditions of nutrition: (1) On a diet of protein and fat of insufficient caloric value, while if most of the fat in this diet were replaced by carbohydrate there was no fall in the output; (2) in starvation during the first few days; and (3) on a diet of carbohydrate and fat. They consider that the cause of the diminution is "the interaction of protein and carbohydrate metabolism."

4. This article by Parkinson and Rowlands should be read by all who swear by strychnine as a cardiac stimulant. A careful study of the action of this drug in fifty cases of severe cardiac failure failed to show any effect whatever on the pulse rate, respiratory rate, blood pressure or general symptoms. The dose was one-fifteenth grain given subcutaneously, and the observations were continued for an hour after a single dose.

5. Sutherland and Paterson describe what they claim to be a new disease of the brain, on the basis of two cases. The symptoms during life were striking, and pointed to complete failure of development of the cerebral cortex, viz., absolute lack of intelligence, sight or hearing, and of sensation. Tonic and clonic spasms were a constant feature, the most frequent position being one of opposthotonos with pleurosthotonos, with the arms flexed and the legs extended. Tachycardia and tachypnea were very marked. At the autopsy there was almost complete aplasia of the cortex, with the exception of the occipital lobes. The vacant space was filled by a large amount of fluid in the pia-arachnoid.

6. Wallis throws new light on that remarkable disease, sulphemoglobinemia. The condition is characterized by cyanosis, often intermittent, headache, weakness and constipation. In methemoglobinemia the symptoms are the same except that there is diarrhea instead of constipation. The diagnosis depends upon the spectroscope examination of the blood, which shows a single band in the red in each of these two conditions. The band due to sulphemoglobin remains after the addition of ammonium sulphide to the blood, while that due to methemoglobin disappears. Wallis found a very strong reducing substance in the blood serum in all his five cases, the nature of which was not determined. Furthermore, the saliva in all contained large amounts of nitrites, and on cultivation yielded constantly a nitroso-bacillus (*i.e.* a bacillus yielding nitrites on cultivation in protein-containing media). A powerful reducing substance was also found in the cultures. [W. T.]

1. Payr reports preliminary observations on the treatment of intestinal disturbances with the electromagnet. Payr has found that reduced iron oxide given in capsules is insoluble in neutral or weakly alkaline solution and is therefore not absorbed from the intestinal canal. In this way the intestines become rendered magnetic and in experimental animals were drawn in the direction of an electro-magnet placed on the abdominal wall. Experimentally, Payr found that the large intestine, stomach, or loops of small intestine could be moved in any desired direction, and that it was possible to break up artificial adhesions induced by iodine. His observations were controlled by x-ray plates. The process was harmless, since the animals showed no toxic manifestations, and as the intestines so treated showed no abdominal histological changes. Identical studies were made on a few patients. The results confirmed those made on animals, but as the technic was not perfected, Payr does not describe them in detail. Payr believes that by magnetizing the intestines in such fashion, much assistance may be derived in the treatment and diagnosis of intestinal adhesions. Future work will determine the value of his preliminary notes.

8. Dunzelt has devised a stain which may be used in an ordinary white blood counter to differentiate the types of leucocytes without coloring the red corpuscles. Its advantages are its simplicity and accuracy of staining. [R. F.]

ARCHIV FÜR KLINISCHE CHIRURGIE.

29. ALAPY, H. *Resection of the Knee-joint in Children.*

24. Körte's article is a detailed review of the treatment of cancer of the large intestine. His conclusions are as follows: (1) The particular dangers of resection of the large intestine, *i.e.* collapse and peritonitis, are due at one time to the peculiar anatomical relations of the portion of the intestines, at another time to the difficulty of handling its contents. (2) In acute obstruction it is possible to attain the drainage of the intestine only by means of colostomy; the radical operation must be done later. 3. In chronic obstruction, as well as in case of uncertain nourishment of the intestinal ends, the bringing out and suturing of the loops to the abdominal wall is the safer though slower method. (4) With sufficient drainage, good blood supply and apposition of the ends without tension, primary resection and suture are indicated. (5) The different anatomical relations of each part of the large intestine require correspondingly different operative technic. (6) The likelihood of cure is favorable.

7. Of the palliative operations, enteroanastomosis is the best procedure provided there is no obstruction. In cases with obstruction, colostomy is the best method. Colectomy and enteroanastomosis should be done secondarily to drainage of the intestine.

26. Nunberg, from a study of the cases of intracranial hemorrhage in Kraske's clinic, concludes that epidural hemorrhage can cause death without giving any of the classical symptoms of increased intracranial pressure. Certain other signs appeared, however, among which may be noted motor unrest and disturbance of the oculomotor nerve. He believes that exploratory trephine or puncture should be done more frequently, and that such procedure has been without ill effect in Kraske's clinic. [G. G. S.]

1. Hering states that cardiac insufficiency comprises not only diminished contractility, but also any other change affecting its function, as, for example, hyperirritability. The early symptoms of cardiac

weakness are largely subjective, and are often overlooked. Irregularity, extra systole and dropped beats are all early symptoms, and denote, besides loss of contractility, less power to generate and transmit impulses. Often these symptoms are accompanied by areas of hypersensitiveness in the skin, as Mackenzie has pointed out. The author speaks of these symptoms as the economic symptoms, and believes that they signify loss of tonus. In syphilitic aortitis, they denote either beginning occlusion of the coronaries or involvement of the aortic cusps. The author lays great emphasis on the importance of searching for these economic symptoms in all cases, and in establishing their presence or absence in the presence of other symptoms of cardiac disease.

9. Wolff's patient was a child nine days old when symptoms first developed. It was given 300 units of tetanus antitoxin during three days. The first dose of serum was injected near the umbilicus, the rest in the abdominal wall, part subcutaneously, part intramuscularly. Chloral, 0.5 gms., was administered by rectum daily for eighteen days. The maximum dose given in one day was 1.5 gms. The child was kept in profound stupor, and was fed through a stomach tube. The author believes that the profound narcosis conserved the child's strength, and allowed the administration of nourishment. After the eighteenth day the chloral was reduced to 0.25 gm. On the twenty-seventh it was omitted and natural feeding begun. [C. H. L., JR.]

1 and 2. Hirsch's article is a discussion of the theoretical causes of arteriosclerosis.

Loeb reports the production of arteriosclerosis in dogs; the first time the lesion has been produced in animals other than rabbits. He has demonstrated that lactic acid may be instrumental in producing the condition, a finding of importance in view of the fact that muscular work greatly increases the lactic acid content of the blood. Loeb suggests that this increased production may be combated by avoiding extreme exertion and by dietetic limitation, or that the action of the acid on the arteries may be in some degree neutralized by increasing the ammonia content of the blood.

4. The author has collected 163 cases of tuberculosis of the bones and joints in which careful bacteriological examinations were made. Of these, only 4 cases showed the bovine type of bacillus. In marked contrast are the findings of Frazer, who in 70 cases found 41 of the bovine type, 26 of the human type, and 3 of mixed infection. [C. H. L., JR.]

Miscellany.

REPORT OF BRITISH ROYAL COMMISSION ON VENEREAL DISEASES.

THE British Royal Commission on Venereal Diseases, which was appointed as a result of the action taken by the International Medical Congress at its meeting in London last August, has recently issued its first official report of its first two meetings on Nov. 7 and 10. Preliminary evidence was given by Dr. Stevenson from the general register office, and statistic evidence by General May as to the prevalence of venereal diseases in the Navy:—

"Dr. Stevenson thought that although the quality of certification generally was improving, there undoubtedly existed a reluctance on the part of medical practitioners to certify venereal diseases as a cause of death, and that consequently the figures contained in the report were minimum figures. He agreed also that there were doubtless many cases of death indirectly due to venereal diseases which are not demonstrated by the tables of the report. At the same time he considered that although the figures do not express the facts, they bear some relation to the facts, and must be regarded as having a distinct comparative value. For instance, he attached importance to figures showing that the death-rate from syphilis in London is four times as high is in the rural districts, and that in descending the scale from the densely populated to the rural districts the death-rate becomes progressively lower.

Dealing with the question of improving certification, Dr. Stevenson strongly advocated a general system of confidential certification under which certificates of the cause of death would not be handed over to the surviving relatives.

"The director-general of the Navy Medical Department gave figures extending over the period from 1905 to 1912. These figures showed evidence of decline both in regard to syphilis and gonorrhea. The figures of the number of cases, and of the number of days lost through sickness for 1912 showed a far more accentuated fall as regards venereal diseases than for any other disease.

"The director-general considered that the reduction in the figures might be due rather to the better education of the sailor in health matters than to the diminution in the prevalence of diseases in the ports. He thought that the men had absolute confidence in their medical officers, and that concealment of the disease was practically non-existent. It is the practice in the navy for medical officers to give lectures on hygiene to the men, and this system was beginning to show very good results, and the admiralty had great hopes of it. With regard to invalidings from the service on account of venereal disease, the director-general thought that the rather sharp fall in

1911, which was disclosed in the tables, should be attributed to improved methods of treatment."

FREE PUBLIC LECTURES ON MEDICAL SUBJECTS.

THE faculty of medicine of Harvard University offers a course of free public lectures, to be given at the medical school, Longwood Avenue, Boston, on Sunday afternoons, beginning Jan. 4, and ending May 10, 1914. The lectures will begin at 4 o'clock and the doors will be closed at five minutes past the hour. No tickets are required. The schedule of lectures is as follows:—

Jan. 4—Dr. W. B. Cannon, Recent studies of the bodily effects of fear and rage.
Jan. 11—Dr. John Lovett Morse, Rational infant feeding.
Jan. 18—Dr. J. E. Goldthwait, The effect of habits of posture upon health.
Jan. 25—Dr. R. B. Greenough, The tumors and diseases of the breast. (To women only.)
Feb. 1—Dr. J. S. Stone, Some surgical diseases of childhood and their causes.
Feb. 8—Dr. A. Coolidge, Jr., Adenoids and tonsils.
Feb. 15—Dr. Charles S. Minot, Microscopical mechanisms of the brain.
Feb. 22—Dr. E. W. Taylor, Some Causes of nervous instability.
March 1—Dr. William P. Cooke, Tooth preservation in children and adults.
March 8—Dr. Charles J. White, Skin nostrums.
March 15—Dr. E. H. Bradford, Chairs, backache and curved spine.
March 22—Dr. Charles H. Williams, Spectacles and eye-glasses. Their use and abuse.
March 29—Dr. E. P. Joslin, Diet in relation to diseases of the kidney.
April 5—Dr. Clarence J. Blake, Aid for the deaf.
April 12—Dr. E. E. Southard, Eugenics versus cacogenics.
April 19—Dr. F. S. Newell, The hygiene of pregnancy. (To women only.)
April 26—Dr. J. Bapst Blake, The diagnosis and immediate treatment of lesser injuries, including the use and abuse of antiseptics.
May 3—Dr. W. H. Smith, Arteriosclerosis.
May 10—Dr. E. H. Nichols, The sexual instinct; its use and abuse. (To men only.)

APPOINTMENTS.

DR. LIVINGSTON FARRAND, professor of anthropology in Columbia University, has been recently elected president of the University of Colorado.

DR. WILLIAM JOSEPH GALLIVAN, of South Boston, chief of the division of child hygiene in the Boston health department, has recently been appointed by the Mayor to the vacancy on the Board of Health left by the resignation, over two years ago, of Dr. Samuel Holmes Durgin.

RECENT DEATHS.

DR. JAMES P. STEDMAN, who died Dec. 24 in Brockton, Mass., was born at Yarmouth, N. S., in 1857. He received the degree of M.D. in 1882 from Boston University Medical School, and since 1892 had practised his profession in Brockton. He was a member of the American Institute of Homeopathy and of the Massachusetts Homeopathic Medical Society. He is survived by his widow, by one daughter, and by one son.

DR. EDGAR MARTINDALE HERMANCE, a prominent physician of Yonkers, N. Y., died from pneumonia on December 22, at the age of 59 years. He was a native of New York City, and was graduated from the College of Physicians and Surgeons in 1878. He had served as commissioner of public safety and as president of the board of health of Yonkers, and at the time of his death was consulting surgeon to St. John's Riverside Hospital and the Westchester County Hospital.

DR. WILLIAM C. BARTRAM, of Newburgh, N. Y., assistant surgeon and radiologist to St. Luke's Hospital in that city, died on December 17 from septicemia resulting from a needle prick received while operating a few weeks previously. He was 34 years old and was graduated from the medical department of Columbia University, New York, in 1904; after which he took a course of post-graduate study in Vienna.

DR. GARY H. WOOD, of Antwerp, N.Y., died from Bright's disease on December 18, at the age of 50 years. He was for some time a member of the Legislature from Jefferson County.

DR. RICHARD G. P. DIEFFENBACH, of Newark, N. J., died from cerebral apoplexy on December 17, at the age of 62. He was attending surgeon to the Newark German Hospital and treasurer of that institution.

SOCIETY NOTICE.

THE BOSTON SOCIETY OF MEDICAL SCIENCES.—The next meeting will be held on Tuesday evening, Jan. 6, 1914, in the amphitheatre of the Peter Bent Brigham Hospital at 8.15 o'clock. The meeting will be conducted by the Historical Club of the Harvard Medical School (Mr. William J. Kerr, secretary).

Papers will be presented as follows:—

Dr. Thomas Ordway, "Hodgkin's Disease." Exhibition of a case.

Dr. L. W. Hackett, "The Medical Side of Benjamin Franklin."

Dr. E. E. Southard, "Some Neuropathological Worthies."

THOMAS ORDWAY, *Secretary and Treasurer*,
Harvard Medical School.

Original Articles.

THE EFFECT OF DIGITALIS ON THE BLOOD PRESSURE AND PULSE PRESSURE IN THE PRESENCE OF CARDIAC DECOMPENSATION.

BY CHARLES H. LAWRENCE, M.D., BOSTON,

Assistant Visiting Physician, Massachusetts General Hospital; Assistant in Clinical Medicine, Harvard Medical School.

From the West Medical Service, Massachusetts General Hospital, Dr. Richard C. Cabot, Chief of Service.

IN the majority of writings upon digitalis, it is stated that one effect of the drug is to raise the systemic blood pressure[1] and that for this reason its use is contraindicated in those conditions in which an increase of circulatory tension might give rise to unfortunate results. Thus Allbut,[2] writing in a recent system of treatment, states that, "In angina pectoris digitalis and its kind are for obvious reasons to be eschewed." Likewise, it is the opinion of a large number of writers that in the hypertension of arteriosclerosis and chronic nephritis there exists a strong contraindication to the administration of the most efficient cardiac tonic known. As a result of this teaching, digitalis is not administered in many cases of cardiac decompensation because there is a co-existing arteriosclerosis, hypertension, or angina pectoris.

It is an undoubted fact that digitalis does raise the blood pressure in animals.[3] There is reason to believe that it has the same effect when administered to healthy individuals. The basis for this belief is found in the recent work of Marvin,[4] who administered tincture of digitalis to a series of medical students. He found that a single dose of the drug (14 minims) caused no rise in pressure for an hour and twenty minutes after its administration, but that there was a marked rise later, reaching its maximum in five hours, and reaching normal by a gradual fall occupying fifty hours.

It is upon the basis of this work on animals and normal individuals that the conclusion has been reached that digitalis causes a rise in blood pressure when administered to individuals suffering from cardiac decompensation. Such observations, however, as have been reported on this question seem to show that this is not the case. Price[5] made observations on the systolic pressure of twenty-one patients who were receiving therapeutic doses of digitalis, and noted a rise in pressure in only one instance. He concludes from his work that "judged by the methods in use for observing the blood pressure clinically, the internal administration of digitalis does not raise the blood pressure in man by constricting the peripheral arteries." Of a similar tenor are Mackenzie's conclusions.[6] "Contrary to expectations," he found a rise in pressure following the administration of digitalis "only in exceptional cases," even though he repeatedly pushed the dose until distinct evidence of its physiological action was produced. "Even when the patient was greatly benefited by the drug," says Mackenzie, "I have frequently seen little or no evidence of a rise in blood pressure."

It is the purpose of this paper to contribute to our knowledge of the effect of digitalis when administered to patients with cardiac decompensation from various causes. Observations are reported on twenty-five cases taken at random from the records of the Massachusetts General Hospital. In the majority of cases these readings were made by the house officers in the routine treatment of the case, and without special reference to the effect of digitalis. In five cases, observations were made twice daily by the writer. Both systolic and diastolic pressure were recorded. The cases include valvular cardiac disease, arteriosclerosis with myocardial degeneration, angina pectoris, and chronic nephritis with hypertension. All the patients had more or less cardiac decompensation, as shown by the presence of one or more of the classical symptoms of that condition. The digitalis was administered in the form of digipuratum in all but a few cases. These received an active tincture. The accompanying table gives a brief description of each case, together with the average blood pressure readings before, during, and immediately after the use of the drug; also at discharge from the hospital. The presence or absence of diuresis, and the other effects of treatment, are also noted.

CASE 1. Male, 57 years. Arteriosclerosis. Marked edema of feet and legs. Urine at entrance, ℥50. Given digipuratum, two tablets daily for six days. Blood pressure: before digitalis, S. 185, D. 110; tafer digitalis, S. 190, D. 120; at discharge, S. 200, D. 120. No diuresis from digitalis, discharged relieved.

CASE 2. Male, 49 years. Syphilitic aortitis, Hypertrophy and dilatation of heart, infarct of lung. Shifting dullness in abdomen, marked edema of feet, legs and thighs. Urine at entrance, ℥50. Given digipuratum, nine tablets in four days. Urine rose to ℥65 the fourth day. Blood pressure: before digitalis, S. 200, D. 95; after digitalis, S. 180, D. 85. Discharged relieved.

CASE 3. Female, 45 years. Acute bronchitis, chronic endocarditis of mitral and aortic valves. Slight edema of ankles and shins. Urine at entrance, ℥40. Given digipuratum, two tablets daily for three days, then one tablet daily for four days. Urine rose to ℥70 on fourth day. Blood pressure: before digitalis, S. 145, D. 85; after digitalis, S. 115, D. 75. Discharged relieved.

CASE 4. Male, 26 years. Acute vegetative endocarditis, chronic endocarditis, streptococcus infection of kidneys, syphilis. No edema. Urine at entrance, ℥35. Digipuratum, three tablets daily for seven days. No diuresis. Blood pressure: before

digitalis, S. 140, D. 55; after digitalis, S. 170, D. 50. Discharged not relieved.

CASE 5. Male, 58 years. Syphilis, myocardial weakness, arteriosclerosis, hypertrophy and dilatation of heart. Edema of lungs, liver and legs. Urine at entrance, ℥16. Digipuratum, three tablets daily for nine days. Urine rose to ℥40 on the third day. Blood pressure: before digitalis, S. 175, D. 130; after digitalis, S. 170, D. 110; at discharge, S. 150, D. 95. Discharged relieved.

CASE 6. Male, 60 years. Myocardial weakness. Marked edema of thighs and legs, edema of lungs. Urine at entrance, ℥12 (?). Digipuratum, four tablets daily for four days, then three tablets daily for three days. Urine rose to ℥58 on the fifth day. Blood pressure: before digitalis, S. 180, D. 90; after digitalis, S. 170, D. 90; at discharge, S. 150, D. 90. Discharged relieved.

CASE 7. Male, 67 years. Arteriosclerosis, coronary sclerosis, angina pectoris, hypertrophy and dilatation of heart, terminal pericarditis. No edema. Urine at entrance, ℥35. Digipuratum, three tablets daily for five days, then one tablet daily for eight days. No diuresis. Blood pressure: before digitalis, S. 160, D. 115; after digitalis, S. 160, D. 110; at discharge, S. 160, D. 110. Discharged dead.

CASE 8. Male, 64 years. Syphilitic aortitis, aortic regurgitation. Trifling edema of ankles. Urine at entrance, ℥40. Digipuratum, three tablets in 24 hours. Urine rose to ℥60 on the third day. Blood pressure: before digitalis, S. 150, D. 60; after digitalis, S. 130, D. 45. Discharged relieved.

CASE 9. Male, 53 years. Chronic nephritis, myocardial insufficiency, anasarca. Marked edema of legs, abdominal wall, back and lower part of chest. Urine at entrance, ℥40. Digipuratum, two tablets daily for six days. Urine rose to ℥75 on the fourth day. Blood pressure: before digitalis, S. 200, D. 110; after digitalis, S. 170, D. 95; at discharge, S. 170, D. 100. Discharged relieved.

CASE 10. Male, 53 years. Aortic stenosis and regurgitation, adhesive pericarditis, arteriosclerosis. Marked soft edema of legs. Urine at entrance, ℥50. Digipuratum, three tablets daily for 14 days. No diuresis. Blood pressure: at entrance, S. 160, D. 60; after digitalis, S. 130, D. 50. Discharged dead.

CASE 11. Female, 40 years. Mitral stenosis and regurgitation, auricular fibrillation. Slight edema of lungs, shins and ankles. Urine at entrance, ℥15. Digipuratum, two tablets daily for 11 days. Urinary output thought increased, exact measurement impossible. Blood pressure: at entrance, S. 150, D. 105; after digitalis, S. 120, D. 80. Discharged relieved.

CASE 12. Female, 46 years. Mitral and aortic stenosis and regurgitation, stasis. Left hydrothorax, marked edema of legs and back. Urine at entrance, ℥35. Digipuratum, 11 tablets in five days. No diuresis. Blood pressure: at entrance, S. 130, D. ? twice later during and after digitalis, S. 130, D.? Discharged dead.

CASE 13. Female, 41 years. Mitral stenosis. Slight edema of shins. Urine lost. Digipuratum, two tablets daily for five days. Tincture, m. 10 every six hours for four days. Blood pressure: at entrance, S. 100, D. 80; after digitalis, S. 120, D. 80; at discharge, S. 120, D. 80.

CASE 14. Male, 37 years. Myocardial disease. Double hydrothorax, marked edema of legs. Urine at entrance, ℥40. Digipuratum, two tablets daily for five days, one tablet daily for four days. No diuresis. Blood pressure: at entrance, S. 125, D. 100; after digitalis, S. 110, D. 90; 48 hours after digitalis was omitted, S. 120, D. 100. Discharged dead.

CASE 15. Male, 52 years. Chronic glomerulo nephritis. Slight edema of lungs, ankles and shins. Urine at entrance, ℥35. Digipuratum, two tablets daily for five days, one tablet daily for seven days. No marked diuresis, slight permanent increase in urinary output. Blood pressure: at entrance, S. 195, D. 120; four days after beginning digitalis, S. 180, D. 120; at discharge (digitalis previously omitted), S. 200, D. 120. Discharged relieved.

CASE 16. Male, 43 years. Aortic and mitral disease, broken cardiac compensation. Edema of lungs, legs, and sacrum. Urine at entrance, ℥50. Digipuratum, one tablet daily for six days. No diuresis. Blood pressure: at entrance, S. 125, D. 70; after digitalis, S. 140, D. 50; at discharge, S. 140, D. 50. Discharged relieved.

CASE 17. Male, 54 years. Myocardial weakness, broken cardiac compensation. Edema of lungs and legs. Urine at entrance, ℥45. Digipuratum, two tablets daily for nine days. No diuresis. Blood pressure: at entrance, S. 115, D. 85, after digitalis, S. 115, D. 80; at discharge, S. 125, D. 90. Discharged relieved.

CASE 18. Male, 25 years. Malignant endocarditis. Slight edema of lungs. Urine at entrance ℥15. Digipuratum, two tablets daily for three days. Urine rose to ℥60 on the third day. Blood pressure: at entrance, S. 130, D. 20; after digitalis, S. 130, D. 20; eight days later S. 115, D. 50. Discharged dead.

CASE 19. Male, 47 years. Myocardial weakness, hypertrophy and dilatation of heart, chronic nephritis, uremia. Edema of lungs and ankles. Urine at entrance, ℥25. Digipuratum, three tablets daily for six days. No marked diuresis, but gradual increase of urinary output. Blood pressure: before digitalis, (four readings during seven days), S. 150, D. 120. During and immediately after digitalis, (three readings), S. 125, D. 90. Discharged unrelieved.

CASE 20. Male, 57 years. Arteriosclerosis, myocardial weakness. Ascites, edema of legs and abdominal wall. Urine at entrance, ℥45. Digipuratum, 2 tablets daily for 21 days. Passed ℥200 of urine five days after digitalis was begun. Blood pressure as follows:

Before digitalis, S. 180, D. 125.
48 hours after digitalis was begun, S. 180, D. 95.
96 hours after digitalis was begun, S. 170, D. 80.
7 days after digitalis was begun, S. 175, D. 90.
9 days after digitalis was begun, S. 180, D. 80.
12 days after digitalis was begun, S. 170, D. 90.

20 days after digitalis was begun, S. 185, D. 100. Discharged relieved.

CASE 21. Male, 48 years. Arteriosclerosis, hypertrophy and dilatation of heart, specific aortitis, pericardial adhesions. Edema of lungs, liver, lower legs. Urine at entrance, ʒ35. Digipuratum, 12 tablets in four days. Urine rose to ʒ70 on the fourth day. Blood pressure: at entrance, S. 190, D. 130; after digitalis S. 150, D. 80; at discharge, S. 120, D. 70. Discharged relieved.

CASE 22. Male, 60. Arteriosclerosis, hypertrophy and dilatation of the heart right hydrothorax, moderate edema of lower legs and thighs. Urine at entrance, ʒ35. Digipuratum, average dose for 13 days, three tablets daily. Urine rose to ʒ50 on the sixth day. Digitalis heart block produced. Blood pressure: at entrance, S. 130, D. 90.
24 hours after digitalis was begun, S. 130, D. 80.
48 hours after digitalis was begun, S. 130, D. 80.
9 days after digitalis was begun, S. 120, D. 75.
During period of heart block, S. 140, D. 85.
Discharged relieved.

CASE 23. Female, 11 years. Chronic endocarditis, double mitral disease. Soft edema of both shins. Urine at entrance, ʒ35. Tincture of digitalis, m. 10 t. i. d. for seven days. Urine rose to ʒ70 on the fourth day. Blood pressure, at entrance, S. 100, D. 70; after digitalis, S. 95, D. 60, at discharge, 10 days after digitalis was omitted, S. 100, D. 75. Discharged relieved.

CASE 24. Female, 34 years. Chronic endocarditis, double mitral disease. Urine at entrance, ʒ30. Digipuratum, s. c. two ampules daily for 20 days. No diuresis. Blood pressure: at entrance, S. 95, D. 80. Six days later, S. 95, D. 65. Fifteen days later, S. 95, D. 60. Discharged relieved.

CASE 25. Male, 28 Chronic glomerulo nephritis, hypertrophy and dilatation of the heart, albuminuric retinitis. Marked edema of lungs, liver, legs and thighs. Urine at entrance ʒ30. Digipuratum, two tablets daily for seven days. Urine rose sharply to ʒ60 on fourth day. Blood pressure: at entrance, S. 180, D. 120; after digitalis, S. 160, D. 100; ten days after digitalis was omitted, S. 170, D. 100. Discharged dead six weeks after last reading recorded here.

CASE 26. Male, 32 years. Chronic glomerulo nephritis, hypertrophy and dilatation of the heart, marked edema of feet, legs and thighs. Urine at entrance, ʒ60. Digipuratum, one tablet t. i. d. for six days. Slight diuresis. Blood pressure: at entrance, S. 170, D. 130; after digitalis S. 140, D. 100; at discharge S. 140, D. 90. Discharged much relieved.

SUMMARY OF CASES.

Case.	Age.	Diagnosis	Blood Pressure. Before Digitalis.	After Digitalis.	Diuresis.*	Remarks.
1	57	Arteriosclerosis	S. 185 D. 110	S. 200 D. 120	None	
2	49	Syphilitic aortitis	S. 200 D. 95	S. 180 D. 85	30%	
3	45	Chronic endocarditis	S. 145 D. 85	S. 115 D. 75	75%	
4	26	Ac. and chr. endocarditis Syphilis	S. 140 D. 55	S. 170 D. 50	None	Streptococcus infection of kidneys developed.
5.	58	Syphilis Myocardial weakness	S. 175 D. 130	S. 170 D. 110	100%+	Pressure at discharge, S. 150, D. 95.
6	60	Myocardial weakness	S. 180 D. 90	S. 170 D. 90	400%—	Pressure at discharge, S. 150, D. 90.
7	67	Arteriosclerosis Angina pectoris	S. 160 D. 115	S. 160 D. 110	None	Some relief from anginal attacks.

*The percentage figures in the diuresis column represent the relation of the increase in urinary output to that before digitalis was administered.

Of the 26 cases recorded, 5, or 19%, showed a rise in systolic pressure, the greatest increase noted being 30 m.m. in Case 4. There was present in this case an acute infection, involving the heart and kidneys. Of the group of cases showing a rise in systolic pressure, none showed a diuresis.

Four cases, or 15%, showed no change in systolic pressure. Of these, none showed a diuresis.

Seventeen cases, or 66%, showed a fall in systolic pressure either during or immediately after the administration of digitalis preparations. Of these, 88% showed a diuresis.

Only one case showed a rise in diastolic pressure. There was no diuresis.

Four cases, or 15%, showed no change in diastolic pressure. Of these, 75% showed a diuresis.

Twenty cases, or 74%, showed a fall in diastolic pressure, 63% of these showing a diuresis.

Twelve cases, or 45%, showed an increased pulse pressure, a diuresis occurring in 50% of this group.

Three cases, or 11%, showed no change in pulse pressure. A diuresis occurred in every case in this group.

Eleven cases, or 42%, showed decreased pulse pressure. A diuresis appeared in 81%.

From these figures it appears that in the presence of cardiac decompensation digitalis preparations cause, as a rule, a fall in blood pressure, which is usually associated with an increased urinary output. An increased systolic pressure occurs in a small number of cases, and is not associated with a diuresis. It would appear, therefore, that conditions in which an increased systolic pressure might produce untoward results do not constitute a contraindication to the administration of digitalis, if cardiac decompensation indicates its administration. Such conditions include arteriosclerosis, angina pectoris, and nephritic hypertension. The effect of digitalis on the diastolic pressure is similar to that on the systolic, but as the writer has pointed out in a previous paper,[7] changes in

diastolic pressure are usually of less amplitude than those observed in systolic pressure. For this reason a fall in systolic pressure usually means a diminished pulse pressure. Such a diminished pulse pressure does not necessarily mean a decreased efficiency of the circulation, if the ratio of pulse pressure to maximum pressure is increased. Indeed, such a change may coincide with an increased efficiency of the circulation, as is shown by the fact that in 81% of the cases showing a decreased pulse pressure there occurred a diuresis.

Of the 26 cases studied, 18 were discharged relieved. Of these, 76% showed a fall in systolic, and 86% showed a fall in diastolic pressure during or immediately after the administration of digitalis. It appears, therefore, that such a fall is entirely compatible with improvement in the patient's condition. Two cases were discharged unrelieved, and six cases died. No conclusions can be drawn from this last small group of observations, especially as the changes in blood pressure noted were about evenly divided as to increased or diminished readings.

CONCLUSIONS.

1. The effects of various drugs on the blood pressure, as determined by experiments on animals, do not furnish reliable criteria for the administration of such drugs to man, since the effect may be quite different in the latter.

2. The pressure-raising effect of digitalis noted in animals and in healthy individuals does not occur, as a rule, when the drug is administered to individuals suffering from cardiac decompensation.

3. The cause of the cardiac decompensation does not appear to affect the action of the drug.

4. Digitalis preparations may be safely administered to patients suffering from arteriosclerosis, angina pectoris, or nephritic hypertension, if cardiac decompensation is present; under such conditions it rarely causes a rise in blood pressure.

Report from Centralia, Pa., on Dec. 30, states that Mrs. Mary Horn, who died lately in that city, was locally reputed to be 107 years of age. She is said to have been born in 1806.

RECTAL ALIMENTATION.*

BY HARRY W. GOODALL, M.D., BOSTON.

RECENT investigations of the physiology of the alimentary tract have explained in a large measure why food materials introduced by the rectum fail to satisfy the needs of the body as they do when administered by mouth. At the same time sufficient evidence regarding the ability of the large intestine to absorb nutritive materials has accumulated to stimulate renewed efforts in this direction, with results that are encouraging and promise to be of some practical value.

Inasmuch as there can be no question as to the value of successful rectal alimentation the subject is worthy of a complete review.

PHYSIOLOGY OF DIGESTION AND ABSORPTION.

Digestion and absorption occur chiefly in the small intestine. It is now an established fact that foodstuffs must be disintegrated into comparatively simple fragments before they can be absorbed. Proteins are absorbed as amino-acids, carbohydrates as monosaccharide sugars, fats as soaps, fatty acids, and probably as emulsified fats. One of the chief causes of the failure of earlier attempts at rectal feeding was the fact that the food was not presented in an absorbable form and that the large intestine contains no digestive ferments.

The more recent experiments have had to do with the introduction of compounds which do not require digestion for their absorption. The belief that the body could be nourished under these conditions was encouraged by the experimental proof that amino-acids, simple sugars, fatty acids, glycerol and inorganic salts are built up with apparent ease into living tissue when fed to animals, that not only is excellent nutritive equilibrium maintained, but that animals even gain weight. Work along this line, however, has shown that the problem is not a simple one. While the mucous membrane of the entire alimentary tract from the mouth to the anus is an absorbing surface, and while osmosis and diffusion play a part in the process of absorption, of far greater consequence is the selective activity of specialized epithelial cells which are found only in a portion of the alimentary tract, chiefly in the small intestines. In general it may be said that osmosis and diffusion play a more important part in the absorption of water and salts, while the selective action of the cells is chiefly concerned in the absorption of organic material. Again the path of absorption is not the same for all substances which are absorbed: fats are taken up by the lymphatics, while practically all other substances are absorbed by the blood vessels.

* Read at the quarterly meeting of the Staff of the Boston Dispensary, October 3, 1913.

With these facts in mind the physiological problems of the large intestine may be considered.

NORMAL PHYSIOLOGICAL FUNCTIONS OF THE LARGE INTESTINE.

As an Excretory Organ. The work performed by the large intestine is chiefly excretory. For besides the fact that the digestive residue remains in this part of the alimentary tract for twenty-two hours and is then excreted, the walls of the large intestine play an important part in the excretion of lime, magnesium, iron and phosphates. Furthermore, it is the main channel of excretion for certain substances which are not normal food constituents, such as bismuth and mercury, and it is probable that ulcerations in the large intestine may be due to this excretory function. This is certainly so in the case of mercury.

As a Digestive Organ. Normally the large intestine plays a very minor part in digestion. Solitary glands and follicles of Lieberkuh have been demonstrated, but for the most part the mucous membrane shows the typical goblet cells which secrete mucus. The presence of any digestive ferments is very doubtful and would be unnecessary since absorption is very complete in the small intestine. Digestion may, however, occur in this region provided digestion is not complete in the small intestine as some of the enzymes secreted in the small intestine may pass along with the bowel content. Furthermore, carbohydrates and proteins, if present, are attacked and disintegrated by the bacteria normally present in the large gut.

As an Absorbing Organ. As an absorbing organ it is of little importance, as might be expected in the absence of villi and valvulae conniventes. Normally no absorption of food material worth mentioning takes place. It has been estimated that about 500 c.c. of water pass the ileo-cecal valve in twenty-four hours, and of this about 400 c.c. are absorbed.

In considering the results of animal experimentation it must be borne in mind that with dogs and some other animals absorption is never completed in the small intestine, but continues in the large intestine, carbohydrates and fats being absorbed more rapidly than protein.

EXPERIMENTAL ABSORPTION FROM LARGE INTESTINE.

From the accumulated evidence it may be briefly stated that water and salts are rapidly taken up by the large bowel. Amino-acids and monosaccharide sugars are absorbed much more slowly than they are from the small intestine, but yet promptly enough to permit of the introduction of sufficient quantities for nutritional requirements. Fats are absorbed too slowly to be of value. Alcohol is readily absorbed.

Unfortunately, certain difficulties arise when an attempt is made to apply this experimental knowledge to actual practice. Exact experimental work with such amino-acids as glycocoll and alanine has been successfully made, but aside from the fact that the preparation of these bodies is difficult and expensive, our knowledge as to the particular kinds and the proportions of these bodies requisite for nutrition is as yet very fragmentary. Attempts have been made to overcome this lack of knowledge by predigesting proteins with pancreatic extract and by introducing pancreatic extract with the nutrient enemata, but the limitations of this artificial digestion and the irritation resulting from bacterial decomposition make such attempts impractical. Hence, for practical purposes at the present time, the only rational enemata would consist of water, salts, simple carbohydrates and alcohol.

RECTAL ALIMENTATION.

The introduction of enemata constitutes an abnormal occurrence and new conditions arise, which in the main are irritative in character and which necessarily modify the rate and ease of absorption of the substance introduced.

First of all enemata not only simulate normal peristalsis, but anti-peristaltic waves are always set in motion. With small enemata the injected material is seldom carried beyond the ileo-cecal valve, but with large injections it may be carried to the small intestine and even to the stomach. If the material is carried to the small intestine it is promptly absorbed, but in practice one can place no dependence upon this occurrence.

Aside from the mechanical irritation caused by enemata, a thing which in itself often makes repeated injection impossible, the material itself may act as a chemical irritant. This may result from the osmotic action of the material injected, and this is especially true if concentrated solutions are injected, or the reaction of the solution may be such as to irritate, or the chemical changes resulting from bacterial action may cause the formation of acids, gases, etc., which are irritative.

This not only makes it more difficult to retain the enema for the long period of time (at least one hour) necessary for absorption but it may actually prevent absorption, as the mucous membrane of the entire alimentary tract is capable of exercising a protective function whereby it inhibits or prevents the absorption of irritative or poisoning substances.

Sugar Enemata. Most investigations have been made with dextrose in solutions varying between 3% and 16%. Usually there is resulting irritation, especially with the more concentrated solutions, and if 16% is exceeded diarrhea always results. An isotonic 5.4% solution is said to be less irritating, and pure dextrose is preferable to commercial glucose. Better results

are in any case obtained by beginning with the weaker solutions and gradually increasing.

Experiments made with enemata of 500 c.c. volume retained five hours, followed by a rest of one hour, showed that with 3% dextrose solution from 42 gm. to 52 gm. dextrose were absorbed. With 10% solutions 157 gm. to 163 gm. dextrose were absorbed, and with 15% solutions 144 to 193 gm. dextrose were absorbed in twenty-four hours. The amount of sugar destroyed by bacteria under these conditions has been shown to vary between 0.5% and 1%, and is therefore negligible. These results have been confirmed, and it seems possible to provide in this manner about one-third of the total number of calories required to maintain the body while at rest with dextrose enemata.

Alcohol Enemata. Alcohol is probably absorbed more readily than dextrose when given in concentration between 5% and 10%. Owing to its high caloric value it would be very desirable in certain cases. Like dextrose, it is irritating, but it is less so in the weaker solutions than in the stronger. Absolute alcohol is the best form to use. When added to a dextrose enemata it apparently does not increase the irritation and greatly increases the fuel value of the enema.

It has been shown clinically that enemata of the following proportion, yielding 555 calories, are practically completely absorbed in eight hours.

Dextrose	50 grams
Absolute alcohol	50 grams
Water	1000 c.c.

If larger enemata with the same proportions are given, or if the concentration of enemata of this volume are increased, then absorption is not complete.

Water and Salt Enemata. It has been repeatedly shown that water is rapidly absorbed from the large bowel. Likewise experiments have shown that salt is absorbed from the rectum quantitatively almost as completely as in the case of oral administration. Clinical experience has agreed with these findings and it is only necessary to add that in any case where a salt poor diet is indicated salt enemata should not be employed.

Indication for Nutrient Enemata. At present, alcohol and simple sugars are the only practical nutrient materials available for rectal alimentation, and their successful administration would be of the greatest value in any acute case, medical or surgical, in persons that would suffer from the effects of temporary withdrawal of food and in subacute or chronic cases in which nourishment by mouth is impossible or inadvisable. Clinical experience, however, teaches that the resulting irritation and exertion often make their employment inadvisable. This is especially true in cases associated with emaciation and general weakness, inasmuch as marked discomfort, distress, and exhaustion may accompany the retention of the sugar enemata. Disregarding the introduction of drugs by rectum there are certain cases in which the prompt introduction of dextrose may be of distinct therapeutic value, and if for any reason it cannot be taken by mouth, enemata may be employed.

These cases may be classified as follows:—

1. Simple exhaustion from any cause where recovery is doubtful, as exposure to cold, starvation, etc.

2. In some acute infections during critical periods, based upon the present theory that sugar is important for febrile conditions and that the heart muscle is augmented by dextrose, especially advised in septic conditions.

3. As an antidote for certain poisons, as chloroform, alcohol, or some other poisons which cause fatty livers, since it has been shown experimentally that the fatty changes can be prevented by giving sufficient quantities of glycogen forming material. In the case of phosphorous poisoning dextrose fails, but levulose is said to be efficient.

4. In diabetic acidosis and in acetonuria from any cause.

In any of these cases, however, if the demand for sugar is urgent it is promptly and more satisfactorily supplied by subcutaneous or intravenous injections. Isotonic 5.4% solutions injected under the skin of the thighs can be given with impunity and considerable quantities of 10% solutions have been given to human beings without harm and with practically no local discomfort.

Given intravenously, a dose of ½ gm. dextrose per kilo is sufficient for its tonic effect and ordinarily the dose should never exceed 1 gm. per kilo. It may be given in concentration varying between 3% and 10% without harm, but the injection should be given very slowly, drop by drop if possible, inasmuch as more sugar can be taken without the occurrence of glycosuria and without harm if this caution is observed. The purest dextrose obtainable should be used, dissolved in water, plain saline or, preferably, Ringer loche solution.

The following solution is advised in children and very weak adults:—

Dextrose	55.0 grams
KCl.	0.2 grams
$CaCl_2$	0.2 grams
$NaHCO_3$	0.1 grams
Aq. Dest. qr.	1000.0 c.c.

Dextrose Enemata in the Treatment of Diabetic Acidosis. It has been stated that diabetics tolerate sugar better by rectum than by mouth. Experiments in which the sugar is absorbed by the hemorrhoidal vessels, thus avoiding the liver, show fairly rapid absorption without glycosuria. Likewise, it has been claimed that the injection of isotonic 5.4% solution of dextrose into the general circulation is better tolerated than when

an equal amount is injected into the portal vein. Equally competent observers doubt the accuracy of these conclusions, believing that the explanation lies in the slow absorption of the sugar and not in the avoidance of the portal circulation. Without further experimental evidence it cannot be concluded that the greater part of sugar enemata does avoid the liver or that sugar is better tolerated when thus introduced by rectum. Clinical experience has failed to yield any positive evidence on this point. It is reported on the one hand that with the same quantity of sugar given by rectum as by mouth, the acidosis subsides and the glycosuria diminishes; on the other hand, cases are reported in which the glycosuria is not favorably influenced, and in certain instances a marked acidosis has developed when sugar by mouth was withdrawn and the same quantity given by rectum.

OTHER FACTS REGARDING ENEMATA.

Dextrine is said to be preferable to dextrose, as it irritates the rectum less. Its ultimate absorption compares favorably with dextrose, although more time is required. Inasmuch as infant foods consist largely of dextrin it is more easily obtainable.

Much has been said regarding the advisability of the drop method in giving enemata, but the preference of the patient must be always taken into consideration. Absorption is slower by the drop method, consequently this method is preferable in cases of diabetes.

Whenever repeated enemata are given it is essential to note with accuracy the quantity of fluid injected. This is especially true in unconscious or collapsed or extremely debilitated persons, since in such cases it may happen that absorption is retarded or fails altogether, with the result that the fluid finds its way into the small intestine and stomach, and if large quantities are injected these organs may become distended, giving rise to urgent symptoms.

The addition of ten drops of tincture of opium to the enemata may allay the mechanical irritation somewhat and does not delay absorption to any degree.

It has been claimed that nutritive enemata cause a reflex secretion of gastric juice which contra-indicates their employment in cases of gastric ulcer. Experimentally a flow of gastric juice of a half hour's duration has been shown to follow enemata. This corresponds to the period of psychic secretion; consequently it is attributed to the desire for food rather than to a reflex from the rectum. No secondary secretion of gastric juice has been noted.

A STUDY OF LEUKEMIA.*

BY ALEX. M. BURGESS, M.D., BOSTON,

Director of Pathological Laboratory, Montreal General Hospital: Assistant Professor of Pathology in McGill University.

Montreal General Hospital, Pathological Laboratory.

LEUKEMIA is ordinarily defined as a disease characterized by an enormous increase in the number of leucocytes in the circulating blood. Some of the familiar facts concerning the disease are as follows:—

Its course may be chronic, lasting from six months to several years; or acute, from a few weeks to six months. The termination is invariably fatal. The chronic cases are much the more common, and the diagnosis is readily made. The acute cases, on the other hand, although at present they are much more often recognized than they formerly were, are comparatively rare. They are characterized by severe anemia, weakness and a tendency to hemorrhage.

An interesting feature of acute leukemia is that the patients often present some evidence of infiltration of the normal tissues outside the blood vessels by the white cells from the circulating blood. These "leukemic infiltrations," so-called, may be demonstrable only on microscopical examination of the various organs, or they may be sufficiently prominent to be easily recognized as definite tumors. Sometimes they are large and numerous enough to be the most striking clinical feature of the case. Many of these tumors are on section of a definite green or greenish color, and to such the name "chloroma" has been applied. The relation of chloroma to the leukemic process has been but recently demonstrated.

* Received for publication, November 5, 1913.

In dealing with a case of leukemia, the practitioner ordinarily classifies it as either myelogenous or lymphatic in type, according as he finds granular or non-granular mononuclear cells predominating in the blood picture. Some cases in which the cells appear to be more or less equally divided between these two types, and in which many cells are rather indeterminate in character, are called "mixed-cell leukemia." These have been regarded as evidence that the myelogenous and the lymphatic types of leukemia are by no means separate entities, but that the leukemic process represents a disease of all the hematopoietic tissues.

What may be considered as the opposite to this view, is the idea that there are two definite and separate diseases, viz.—lymphatic and myelogenous leukemia. This conception is founded on the view that the lymphocyte and myelocyte are not so closely related in origin as is ordinarily supposed, but arise in definitely different regions, viz., the lymphoid tissue of the lymph nodes, alimentary tract and spleen in the case of the lymphocyte, and the red bone marrow in the case of the myelocyte.

The microscopical examination of the material from a large number of autopsies, inclines the writer strongly to this idea of the separateness of lymphoid and myeloid tissues. The chief cause for confusion seems to be the fact that the undifferentiated cells of both types are large and pale staining, with vesicular nuclei, and are absolutely indistinguishable one from the other by ordinary methods. The myeloblasts, as Naegeli has named the undifferentiated bone marrow cells, are, therefore, often called "bone marrow lymphocytes." When in the course of a myelogenous leukemia such cells appear in the blood, the picture naturally appears "mixed." When they predominate, the disease is considered "lymphatic."

The writer has pointed out in a previous communication[1] the fact that a large proportion of the cases diagnosed as acute lymphatic leukemia are probably myelogenous; that a certain number of them undoubtedly are, and among this latter group are included probably all those cases giving rise to green nodules, known as "chloroma." If, then, the two types of leukemia are separate processes, the mixed cell cases must be in fact myelogenous, and their blood must contain a sufficient proportion of the non-granular myeloblasts ("marrow lymphocytes") to give the appearance of a mixture of myelocytes and lymphocytes.

Since the publication of the article referred to above, another case of chloroma[2] has come under the writer's observation. In this case, as in the others, the invading cells gave a positive indophenol reaction, and the cytoplasm of a large proportion of them, including many that were actively dividing, was finely granular. The indophenol reaction, which is a test for the presence of an oxydizing ferment, is positive in all cells of the myelocyte series, except the most primitive undifferentiated forms. It is constantly absent in cells of the lymphocyte series. In this case then, as in other cases of chloroma, the process is myelogenous. The blood picture, however, seen in specimens stained by "Wright's" modification of "Leishman's" stain, showed a very large proportion of cells resembling lymphocytes, both large and small, and the clinical diagnosis of acute lymphatic leukemia was made. Sections of the invaded tissue, on the other hand, when stained with eosin and methylene blue showed that these cells, which were supposed to be lymphocytes, did not possess the characteristic lymphocyte nucleus, and were apparently of the same type as the large granular cells present. Furthermore, even in the specimen stained by "Wright's" stain, many of these cells which resembled small lymphocytes contained a few large and small basophilic granules. It is probable that almost all of them were of myeloblastic origin, as all gradations between them and fully developed myelocytes could apparently be traced.

As to the essential nature of leukemia, the limit of our knowledge is reached when it is said that leukemia is, beyond a doubt, a malignant tumor whose cells invade the blood stream and grow there. The clinical course of the disease, with its invariably fatal issue, and all the histological and anatomical evidence, point to this view. That a tumor arising from the cells which give rise to the polynuclear leucocytes should occur cannot be considered unnatural, in view of the fact that from practically every other tissue in the body neoplasms are known to arise. Viewed in this light, leukemia can be considered as comprising two definite tumors: (1) a tumor arising from the lymphocyte, and (2) a tumor arising from the myelocyte. The terms "lymphoblastoma" and "myeloblastoma" are applied to these two tumors respectively to indicate that each arises from the primitive cell of its type (lymphoblast or myeloblast) and can manifest any stage of cell differentiation.

In other tumors there is marked variation, both in the degree of differentiation reached by the tumor cells, and in the tendency to invade normal tissues and form metastasis. For example, the cells of a fibro-sarcoma may produce a fair number of intercellular fibrils, and may resemble closely an adult connective tissue cell. Such a tumor tends to grow and invade slowly. On the other hand, the cells may be larger and closer together and may produce very little intercellular substance, and thus may resemble the younger less differentiated fibroblast. In such a tumor growth is usually much more rapid, and invasion of the normal tissues more marked. In many rapidly growing tumors a large proportion of the cells differ distinctly from any normal type. (They are often larger than the normal cells and usually contain a relatively increased amount of chromatin. Sometimes, giant cells with one or many nuclei are common.) Thus in general it may be said that the

younger and less differentiated the cells of a given tumor, the greater their tendency to invasion, and conversely, the more they resemble the adult type, the less do they invade.

If we apply this idea to the tumors of myelocyte origin, we expect to find cases in which the cells are, most of them, well developed granular cells, which multiply slowly, and rarely, if ever, leave what may be considered the normal habitat of their type, viz., the bone marrow and blood stream. Such cases are those of ordinary chronic myelogenous leukemia. We expect also to find cases in which the cells are, a large proportion of them, undifferentiated, non-granular and sometimes atypical, their growth rapid, and their tendency to invade normal tissues well marked; cases in which, furthermore, the course of the disease is relatively short. We find these cases are those of acute myelogenous leukemia. In many of them it is evident that invasion of normal tissues has gone on to such an extent that definite tumor masses are present. These masses, when green or greenish in color, as is usually the case, are called "chloroma."

Of the three cases of this acute condition which have come under the writer's personal observation, all showed a "mixed celled" blood picture; a definite infiltration of normal tissues, and a rapidly fatal course. In two of them, greenish masses or nodules were present in various organs, and were found microscopically to consist of fairly rapidly proliferating cells, which were identical with those seen in the blood stream. In the other case, infiltration of normal tissue was present, especially in the kidney, but was relatively small in amount, and nowhere gave rise to a green coloration or definite nodules which could be recognized in gross. This case and one of the two others were diagnosed clinically as acute lymphatic leukemia, while the remaining case was from the beginning, considered myelogenous. In all of them, however, the invading cells gave a positive indophenol-oxydase reaction, and in sections a fairly large proportion of the cells were seen to be granular. These three cases, then, are examples of rapidly growing tumors arising from the myeloblast in the bone marrow, and invading not only blood and bone-marrow generally, but also to a marked degree, the normal tissues outside the blood stream.

No acute cases of leukemia, in which the invading cell was undoubtedly of lymphoblastic origin, have come under the writer's personal observation. In the chronic cases, just as in chronic myelogenous leukemia, normal tissues outside the blood stream are rarely invaded. The tumor cells arise in some part of the lymphoid tissue and invade lymph nodes and the blood stream. The cells are—most of them—mature in type and resemble the adult lymphocyte (small lymphocyte). These are the cases of chronic lymphatic leukemia. In certain other tumors of probable lymphoblastic origin, the blood stream is apparently never invaded, and the tumors either invade the surrounding normal tissues locally, metastatize into lymphoid tissue only, or show general metastases into various organs. These cases include the conditions ordinarily spoken of as lympho-sarcoma, pseudo-leukemia and malignant lymphoma. The writer has recently studied a tumor whose cells were apparently lymphoblastic which gave rise to multiple metastases in the liver, spleen, kidneys, lymph nodes, bone-marrow and dura. When all are considered, then, we have, arising from the lymphoblast, tumors which invade blood stream and lymphoid tissue more or less exclusively, giving rise to the clinical picture of lymphatic leukemia, as well as certain other tumors which seldom or never, invade the blood stream.

As far as the question of treatment is concerned, leukemia may be regarded in the same light as other inoperable malignant tumors. Certain agents undoubtedly serve to inhibit the proliferation of the tumor cells, and to lengthen the course of the disease. The chief of these are arsenic, benzol, the x-ray and the radio-active substance, thorium-x.

In general, we may summarize our knowledge of leukemia by saying that it represents the invasion of the blood stream by two distinct types of tumor cells, the one derived from the myeloblast and the other from the lymphoblast. The two tumors, therefore, are of separate and distinct origin. The myeloblastoma arises from the myeloblasts of the bone marrow, which are the parent cells of the polynuclear leucocytes; the lymphoblastoma from the undifferentiated cells of lymphoid tissue. The tumors are usually of slow growth and invade only the blood stream and the tissue from which they arise. More or less invasion of other tissues is characteristic of the rarer rapidly growing forms, which constitute the clinical cases of acute leukemia.

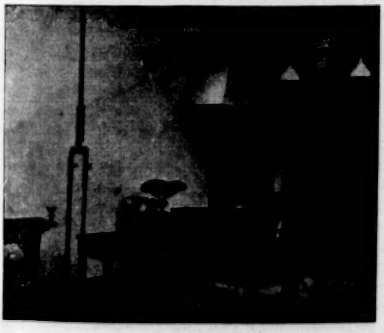
THE OFFICE OF CORONER AND THE MEDICAL SCHOOL AT SYRACUSE.

BY H. G. WEISKOTTEN, M.D., SYRACUSE, N. Y.

From the Department of Pathology of the Syracuse Medical School.

THROUGHOUT the United States medical men are lamenting the fact that in this country there is so little opportunity to perform autopsies. It is a recognized fact that advancements in scientific medicine have gone hand in hand with, and have depended upon advancements in pathology. So today they feel that one of the greatest handicaps to the advancement of medicine in this country is the lack of opportunities to per-



form autopsies. The tables of statistics of autopsies in American and foreign hospitals incorporated in the report of the Public Health, Hospital and Budget Committee of the New York Academy of Medicine show 19.7% autopsies in American hospitals and 83.1% in foreign hospitals. Were there opportunities for autopsies here such as there are in Europe we would not see American internists flocking yearly to Vienna and other European centers.

No medical student who has not had opportunities for performing or seeing autopsies upon cases seen in the hospital can be expected to think anatomically and pathologically; in other words can be expected to practice scientific medicine after his graduation from the medical school. The problem thus is one that presents itself as an all-important one to the medical schools of the country that wish to train doctors who will be worth while.

Until the problem is solved it behooves us to use to the fullest extent every available opportunity which is presented to us. Now one positive way of securing autopsies is through the office of coroner. During the past few years much has been written concerning the ancient office of coroner. Many feel that the coroner's system has outlived its usefulness and should be replaced by the medical examiner's system now in force in Massachusetts and a few other states.

Rather than discuss the propriety of the office of coroner I will outline the system which exists today in Onondaga County which seems to work both for the welfare of the community and to the advantage of the medical school. New York State still maintains the coroner's system.

Two years ago the county built and equipped a morgue at an expense of about thirty thousand dollars. The department of pathology of the Syracuse Medical School volunteered its services and superintended the construction and equipment of the autopsy facilities. As a result the autopsy room is spacious, well lighted and well ventilated and is provided with freezing microtome, microsope, stains, desks and other equipment essential to a modern autopsy room. Adjoining the autopsy room is a laboratory and preparation room. Upon the completion of the morgue, through the efforts of Dean Heffron and other members of the faculty, the writer, one of the members of the department of Pathology, was appointed to a newly created office of county necrotomist at a salary of $1,000 a year. The sole duty of the necrotomist is to perform the coroner's autopsies. These autopsies were formerly performed by the coroner's physicians, all of whom were general practitioners. There was practically no opposition to the creation of the office of necrotomist after one of the members of the faculty explained to the County Board of Supervisors the necessity and the opportunity for scientific autopsies. It seems to us an added advantage that the necrotomist can stay entirely within his sphere and confine himself solely to autopsy work. Coroner Kinne himself has assumed a very generous attitude in relation to the new arrangements and has cooperated to make the new office of county necrotomist a success

Autopsy room in the Onondaga County Morgue at Syracuse, N. Y.

About one hundred and seventy-five autopsies are performed at the morgue in a year. Many of these autopsies are upon hospital cases. When physicians are not satisfied in their own minds as to the diagnosis of cases terminating in death in hospitals they refer the case to the coroner without a diagnosis. The body is then brought to the morgue and an autopsy is performed. Accompanying each body brought from a hospital to the morgue is a clinical history of the case.

The morgue is located within three minutes walk of the medical school. As a result of the present arrangements there is opportunity for special instruction of the student in autopsy technique and in pathology. The class in pathology is taken to the morgue in groups of four and the students perform the autopsies themselves under the supervision of the necrotomist. They write descriptions of the organs and make frozen sections, smears and cultures. The third and fourth year students see at autopsy cases which they have studied in the hospital. Plenty of room, good light and good ventilation permit a student to give his best efforts to the study of autopsy findings instead of being a more or less passive onlooker under unfavorable circumstances.

The morgue also furnishes excellent material for instruction in gross pathology at the school and for the weekly clinical-pathological conferences which are attended by the third and fourth year students.

This paper was suggested by numerous enquiries from other cities in regard to the morgue arrangements at Syracuse. Although not a complete solution of the great problem of increasing the opportunities for autopsies in this country it seems to us that these arrangements offer a very satisfactory solution of the problem of obtaining autopsy facilities for medical students. At the same time it offers to the public the ad-

vantages of carefully performed autopsies and full autopsy records.

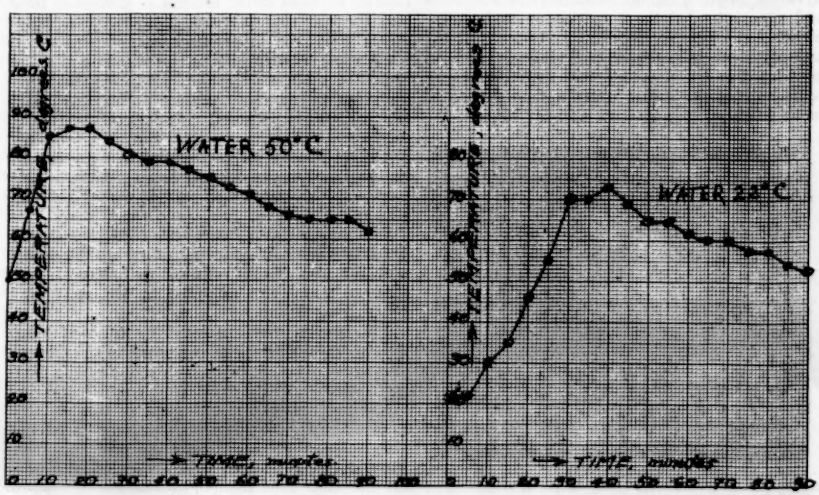
A SIMPLE AND EFFECTIVE METHOD FOR DISINFECTION OF TYPHOID STOOLS.

BY HARRY LINENTHAL, M.D., BOSTON,

State Inspector of Health; Assistant Physician to Out-Patients, Massachusetts General Hospital.

AND

HENRY N. JONES,



Bacteriologist to Massachusetts State Board of Health.

IT is now a well established fact that the immediate destruction of the typhoid organism in the excreta of the typhoid patient is one of the most important steps in the control of typhoid fever. Unfortunately, however, in the vast majority of cases of typhoid fever ill at their homes nothing that might reasonably be called efficient disinfection of stools is carried out.

One of us (H. L.) has had occasion at various times to investigate isolated cases of typhoid or outbreaks of the disease. The instances where he observed any procedure of what might be regarded as a serious effort to disinfect the stools were extremely rare. Only in a few communities in the state does the board of health issue any instructions when a case of typhoid is reported to them as to methods to be used in disinfection of the excreta. It is usually left to the attending physician to instruct the family in the matter. The methods usually in vogue consisted in sprinkling a little chloride of lime or sulphonaphthol over the stool, which was promptly deposited in the water closet or privy without being mixed or without letting it stand. Even in many instances where trained nurses were in attendance the procedure was not any more effective. The use of the disinfectants in such a perfunctory manner simply gives a false sense of security to the family and attendant. Not much need be said of how serious this situation becomes in communities where no public sewer exists and where the excreta are deposited in privy vaults accessible to flies, or, as often happens, when such privies are situated on some watershed.

The bedside disinfection of stools is not as simple a matter as it might appear. The proper utensils are often not available and the treatment of the stool, the thorough mixing with the disinfectant and the necessary exposure of the stool to its action, will in the great majority of cases not be carried out even when detailed instructions are given. Moreover, it has been questioned whether the disinfectants as ordinarily recommended, can be depended upon for thorough disinfection. Dr. Alvah H. Dotty carried on experiments with the various disinfectants recommended for the purpose as they are usually employed. He found that at the end of twenty hours of exposure to the disinfectant but one-eighth of an inch of the fecal mass was disinfected. Heat—boiling water or steam—is the only effective way of dealing with typhoid discharges, but clearly the apparatus needed to do that is not available in households.

A method to disinfect typhoid discharges to be both practical and effective, must be one which should require only such utensils which are available in every household and must be so

simple as to require little intelligent effort on the part of the attendant. Such a method was described by Dr. Prausnitz of Austria at the Fifteenth International Congress, on Hygiene and Demography, held in Washington in September, 1912. The method was devised by Dr. A. M. Kaiser in the Hygienic Institute of Gratz University. It consists of adding enough hot water to cover the stool in the receptacle and then adding about one-fourth of the entire bulk of quick lime (calcium oxide), covering the receptacle and allowing it to stand for two hours. The hydration of the lime generates enough heat to destroy the typhoid organism.

We undertook to test out this method. In the first place we set out to determine the quantity of heat generated and the length of time the heat is retained. To make the conditions as rigid as possible we used an ordinary tin pail with a loose fitting cover. To a litre of cold water we added from 300 to 400 grams of ordinary commercial quick lime, and the temperature was observed. We found that the lime varied in its action, while in some experiments the temperature would rise to 80° or even to 90° in about ten minutes, in others it would take twenty minutes to one-half hour for the temperature to go up to 75° or over and maintain a temperature of over 60° for one and one-half hours. We found, however, in several observations that the temperature did not go above 55° due undoubtedly to the poor quality of the lime, although it came from the same lot.

If, however, hot water was used, ranging in temperature from 50° to 65° C. it invariably rose to 75° or over in ten minutes, and in twenty minutes it reached 85° and often 90°, and a temperature was maintained over 60° for an hour and a half or longer. We found that the temperature was maintained for a longer period when an earthen vessel was used than in the tin vessel.

Of the many readings that we took using hot water we found that, starting ten minutes after the addition of the lime and continuing for one and a half hours we got maximum temperatures of 90° and minimum temperatures of 58°. The average temperature for the hour and a half period, taking readings every five minutes, was in no case less than 74°.

The accompanying chart shows the temperature readings taken every five minutes for one and a half hours, (*a*) with water 50° C. and (*b*) cold water. These curves may be regarded as fairly typical.

It was clear, therefore, that this process generates enough heat to destroy the typhoid or any other organism, with the exception of spore bearers. The next question was as to whether the heat is sufficiently penetrating to destroy the organisms in the centre of the fecal mass. To determine this we buried in the center of the fecal mass capillary tubes containing living typhoid organisms, distributed over the mass small lumps of lime, about 400 grams, and added enough water to cover the stool, and permitted the mixture to stand for one and a half hours. In all the experiments with the typhoid organisms cold water was used. The capillary tubes were then taken out and broken into a bouillon culture. No growth took place.

CONCLUSIONS.

The addition of about a cupful of commercial unslaked lime and water to a typhoid stool will generate enough heat to kill the typhoid organism. While cold water may often suffice, it cannot be depended upon owing to the variable quality of the lime. Hot water from 50° to 60° C. will always give the desired results. The lime used should be in lumps, broken up in small pieces and distributed over the stool.

We believe that this is a simple, efficacious method and should take the place of the various methods now recommended by local boards of health.

CANCER OF THE LOWER LIP.*

[CANCER CONTROL.]

BY JOSEPH C. BLOODGOOD, M.D., BALTIMORE.

WHAT facts have we today in regard to cancer of the lower lip which should be known to the laity, the general practitioner and the expert surgeon?

In the surgical pathological laboratory of the Johns Hopkins Hospital I have investigated critically about 200 cases, which have been treated in the Johns Hopkins Surgical Clinic, or at the Union Protestant or St. Agnes Hospitals, or cases which have been sent to the laboratory from other sources for diagnosis and record.

In not a single case did a cancer of the lower lip begin in normal skin and mucous membrane. There was always a previous defect, as a rule, present some months before the signs of the development of cancer. In many cases the original, or precancerous, lesion had been observed by the patient for years before the signs of cancer developed. Therefore, there was ample opportunity in every case for the healing or excision of the lesion in its benign state.

We rarely observe on the lower lip congenital subepidermal nodules which later grow and form cancer. These are more frequent on the face and scalp. Any irritation of the skin or mucous membrane gives rise to one of two results: If the epidermis is destroyed there results an ulcer; if this ulcer does not heal we have a chronic ulcer. If the epidermis is not

* Author's abstract of paper read before the Southern Medical Association, at Louisville, Ky., Nov. 20, 1913.

destroyed there is a hypertrophy, both of the superficial horny layer and of the papillary epithelial body as a downgrowth. This hypertrophy gives rise to a gross lesion variously called "wart, papilloma, corn, callosity"; each of these varies slightly in its gross appearance, explaining perhaps the different terms.

In both resulting lesions, the ulcer and the wart, there is epithelial activity of a far greater degree than in the normal skin. What the factor is which starts the epithelial activity giving rise to a local growth called cancer, we do not know.

I have had the opportunity to investigate critically fifteen benign precancerous lesions of the lower lip. In the first place it is interesting to note that only five of these were observed previous to 1908; the remaining ten have come under my observation since 1908. Practically every one of these new cases can be traced to an educational suggestion.

In all of these cases a v-shaped piece of the lower lip was excised, giving the lesion, except in one instance, a good margin. All of these cases have been traced. In 14 there has been no recurrence. In the one case (a burn from smoking) the margin was insufficient; the lesion was excised later and has not recurred. The scar from the operation in these cases is not mutilating. The case just noted, in which there was a recurrence, was one sent to the laboratory for diagnosis.

Smoking seems to be the most common etiological factor. In five cases we have the typical burn from smoking a pipe or a cigar. This I will describe later in detail in its relation to cancer. There are two benign ulcers from smoking, undoubtedly the original lesion was a burn. There were two ulcers, one from the wound and one secondary to a pimple. In six cases the result was a wart. The etiological irritating factors previous to the development of the wart were, wound, one case; fever blister, two cases; biting of lips, one case; smoking, two cases.

In nine of fifteen cases the irritation or burn from smoking has produced the precancerous lesion.

The duration of these precancerous lesions is very interesting. In two cases the lesion was present less than one month before it was excised: one a wart from biting the lips, and one a smoker's burn. In the third case the lesion had been present about six weeks—an ulcer of the lower lip associated with the excessive use of tobacco.

In all the other twelve cases the lesion had been present more than six months; in four cases three to four years. Three of these were warts, one a chronic ulcer.

These twelve patients who waited longer than six months took their chances of cancer, as I will show later in discussing the interval of time before the development of cancer in precancerous lesions of the lower lip.

SMOKERS' BURN.

This apparently is a distinct lesion in the gross, and apparently quite distinct microscopically. At the muco-cutaneous border, at the point of contact of cigar or pipe, there appears a small depression, oblong in shape, with its long axis at right angles to the muco-cutaneous line; the color and consistency of the mucous membrane and skin is changed; the tissue looks charred; it is not a scab because it cannot be picked; on palpation this little surface defect is leathery, and not moist and soft as normal mucous membrane and skin. The induration, however, of cancer is absent.

I have had an opportunity to study microscopically such a smokers' burn lesion of four weeks' duration and one of one year's duration. In both cases the charred tissue consisted of degenerated hornified epithelium; beneath this there was a thin zone of epidermis resembling the epidermis one finds in experimenting with the healing of wounds and skin-grafts. That is, there is no papillary body, no hair follicle, or gland. In the burn of four weeks' duration there are still some areas which are not covered with epithelium. In the burn of one year's duration the entire defect is covered with a layer of epidermis, the surface of which is covered with degenerated hornified epithelium. A smokers' burn, therefore, may be only a partial charring of the superficial layers of epidermis, but this must lead to the entire destruction of the epithelium of the epidermis. The charred dead cells remain as a cover and new epithelium grows across, so that if the burn is not continued and there is no other injury, this defect may heal without evidence of ulceration or any discharge.

MALIGNANT WARTS.

During the same period we have observed seventeen malignant warts. All of these cases, except one, have remained well since operation. In nine cases the operation consisted of an excision of a v-shaped piece only; in the remaining eight cases the glands of the neck were also removed. In not a single instance did the glands show metastasis.

In the one case which has not been cured, the wart extended almost from angle to angle of the mouth; it had been present two years. A careful reading of this history and of the operation notes, combined with the pathological report, will show that the wart was incompletely excised. The failure to cure in this case, therefore, was due to the operation, and not to the disease, although the necessary operation in this case would have been mutilating, and this necessary mutilation to cure a malignant wart of the lower lip resulted because the patient allowed the evident warty growth during a period of two years to grow over the entire lower lip.

In two instances the duration of the malig-

nant wart has been two months. In one instance five months; in the remaining cases more than six months; the case of longest duration was ten years.

Apparently a proper local operation is sufficient to guarantee a cure in a malignant wart. For this reason the surgeon need not do any more for such a tumor. As a matter of fact, it will be difficult sometimes to distinguish the malignant wart from the benign. As a rule the wart is larger and may show some ulceration on its surface or base. But the diagnosis of malignancy is a microscopic one.

The same etiological factors are given in the cases which came under observation with malignant warts, as those with benign. Whatever the irritating factor is, the result is a wart.

The importance of the duration of the disease is shown when we come to investigate the fully developed cancer of the lower lip.

There is not a single case of cancer of the lower lip which sought advice within one month after the beginning of the trouble. Two cases came under treatment within two months after the onset of the disease: both of these cases have remained permanently well for more than five years since operation; in both the precancerous lesion was a pipe burn; in both the glands were removed at operation, but did not show metastasis. These two cases demonstrate that carcinoma of the lower lip may develop within two months after the onset of such a simple lesion as a smokers' burn which I have just described, but as yet the patient still has 100% chances of a cure, if the surgery is good.

Among the five-year cases there is but one lesion of three months' duration. This was a fully developed cancer in a smokers' burn, and there has been no recurrence now more than fifteen years since operation.

In those cases which inform us that the lesion has been present from three to six months we find for the first time metastasis to the glands of the neck in which the probability of a cure is but fifty per cent.

With our experience up to date with five-year cases, we may safely say that if the lesion on the lip has been present three months or less, the chances of a permanent cure, if the surgery is good, should be 100%. The lesion should be excised under cocaine with a good margin; it should be studied microscopically; if it proves to be a fully developed carcinoma the glands of the neck should be removed. This operation is by no means a simple one, and should not be performed by an inexperienced surgeon. Unless properly done, it would be better for the patient to have it left undone. In this operation the submental, submaxillary and subparotid glands should be removed *en-bloc*. The submaxillary salivary and a piece of the parotid are included in this dissection. In a later paper I will show that in the great majority of cases this dissection has not been complete enough. Of course, if the glands show no metastasis, the poor dissection makes no difference. Our results show that among 21 cases in which the lip and the glands (no metastases) were removed, there have been 20 five-year cures, or 95%. The failure to cure in this one case was due to a local recurrence. When the glands have shown metastasis, we accomplished cures in but six out of twelve cases, 50%.

Everyone, therefore, should know the potential danger of a simple lesion on the mucocutaneous border of the lower lip, whatever that may be, and if healing is not accomplished within one month the lesion should be excised. As I have just written, warts may become malignant within two months, cancer may develop in a pipe burn within two months, and a fully developed cancer with metastasis to the glands is possible after three months. The greatest danger is from delay of more than six months.

The general practitioner should know that the best treatment is the excision of the lesion with a good margin of healthy tissue. All should know that it is unnecessary and not advantageous to perform such an operation under general narcosis. It had best be done under local anesthesia. All should know and should insist upon a careful microscopic investigation of an excised piece of tissue. If this proves to be a fully developed carcinoma of the squamous or spinal-cell type, the patient should be urged to have the operation upon the glands of the neck. But the general practitioner should know that this operation should only be performed by an experienced surgeon, or not at all.

Surgeons should study the results in their cases of cancer of the lower lip in which the glands showed metastases. My own investigation showed but 50% of five-year cures. In a careful study of the cases I find that in the early operations both submental and subparotid lymph glands were left behind; in recent operations the subparotid. I feel that it is impossible to completely remove these glands without the ligation and excision of the upper portion of the internal jugular vein behind which they lie.

It seems to me that a clear statement such as this in regard to cancer of the lip should be given to the laity and the general practitioner, and surgeons should attempt to keep such records that they will be able from time to time to make a report of this kind.

Colonel Gorgas, M.D., Chief Sanitary Officer of the Panama Canal, has been elected a honorary Fellow of the Royal Sanitary Institute; and Colonel Guy Carleton Jones, M.D., Director-general of the medical service of the Militia of General of the medical service of the Militia of Leith, have been elected Fellows.

Clinical Department.

URETHRAL CHANCRE.

BY I. J. WALKER, M.D., BOSTON.

THE case reported below is interesting from the point of view of diagnosis, also because of the fact that it appeared while the patient was being treated for another lesion of the urethra:

CASE. January 7, 1913, L. R., male, single, age 26. Born in Canada.

F. H. Negative.

P. H. Children's diseases. Pneumonia in June, 1910. Gonorrhea contracted one year ago, the discharge of which has never ceased.

P. I. Comes for treatment of urethral discharge which is seen only in the morning.

P. E. Negative except for examination of genitalia. Meatus slightly reddened and moist. Prostate slightly enlarged on right but not tender. Both urines clear with few shreds.

The patient was given treatment for chronic anterior and posterior urethritis with prostatic infection.

Feb. 10, 1913, patient at visit complained of hard area on underside of penis also of intense burning micturition. Examination showed an indurated area oval in shape on floor of the urethra about one inch from meatus. No enlargement of inguinal glands. On questioning the patient the latter said that five days before on the advice of a friend he had used a urethral injection of strong sulpho naphthol. Immediately after this he experienced severe pain along the course of the urethra which lasted several hours. Later on urinating, he passed some blood and several shreds some an inch in length. The latter undoubtedly were parts of the urethral lining. The following day he had difficulty in urinating because of pain and for the first time noticed the hard area described.

The induration was interpreted as being due to inflammatory tissue. All local treatment was stopped for the time being. The patient acknowledged exposure to venereal disease several times during the last two months.

Two weeks later the patient developed a well-marked secondary rash of syphilis. Wassermann reaction was positive. On Feb. 28, 1913, the patient was given .9 gm. of neosalvarsan intravenously. Two similar doses were given at three-week intervals. The rash had disappeared on March 20. The indurated area gradually diminished in size following the first injection of neosalvarsan and had entirely disappeared by April 25. Since then the patient has been on mercurial treatment.

Urethral chancre, while not common, has been reported by Baye, March, Whitney, and many others. Tanton (*Le Progrès Médical*, Paris, 1910, vol. xxvi, pp. 607 and 619) reviews the subject thoroughly and adds a most complete bibliography.

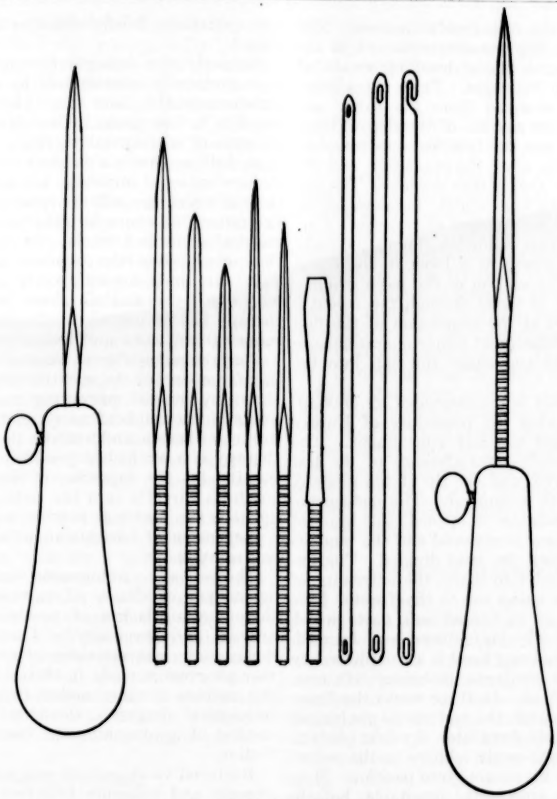
New Instrument.

BONE DRILLING AND BONE PLATING SET.

BY LOUIS A. O. GODDU, M.D., BOSTON.

From the Clinic of the Orthopedic Department of the Massachusetts General Hospital.

IN presenting the following set of instruments the writer appreciates the fact that he does not bring to notice anything surprisingly novel in the device, but varies only in its application. It has always occurred to him that our measures, for drilling holes in bone were, either too complicated, or in some way inadequate for a great many cases. For instance, in the common twist drill we have always to deal with the problem of small gears, also that the drill was not at all times under the immediate control of the surgeon. This perfect control of the drill, it must be conceded, is a thing to be greatly desired.



The accompanying illustration shows the set of drills that has been used by the writer, and some of his associates at the Massachusetts General Hospital, and it seems that the results of their use justify this description and advocating their use.

The drill, as the picture shows is a modification of the common reamer used by machinists. It is triangular in shape, and has a sharp cutting edge at each of its three corners; the points are made especially sharp and abrupt to give strength combined with a cutting edge. It is made of hard tool steel, and capable of penetrating the hard corticle bone which is sometimes met with.

The shank portion of the drill is half round, with the flat surface corrugated so that the thumb screw can set at the desired position of length. This shank can be set in the hole bored in the handle for a short or long drill as desired. The object of this is to meet the different requirements of cases, that is whether the bone is near the surface or a distance from it, the drilling being done with greater ease if the hand is free from surrounding tissue.

The handle is of solid steel with a hole bored in it almost to the top, this is for adjustment as mentioned above. As it is practically solid it is somewhat heavy, but not too much so, just enough to be handled easily and to add weight to the drilling force materially. The thumb screw is purposely large and flat, that it can readily be handled with sterile gloves, also that it gives a point of support for the index finger during drilling.

In the bone plating the shank with the screw-driver is adjusted to same handle. Thus, a bone plate is put in position, the drill makes the hole after which, the drill is left in position and handle removed. The screw-driver is set in the handle, the drill taken out of the bone then the screw is inserted in the hole, and the screw-driver drives it tight.

Bone Drills, ¾ actual size.

With this set the writer, as illustration shows, has bodkins that are used to pass through holes in the bones, to carry tendons or sutures in tendon transplantation work. The bodkins are not tempered but are of sufficient strength to hold, and capable of being molded in the shape desired for the passing of tendons at different points.

The advantages of the drills seem to be:—

1. Different sizes to one handle.
2. The drill is always under the control of the surgeon, while the hole is being drilled.
3. Simplicity and ease of sterilization.
4. Changes that can be made quickly from one drill to another, or to the screw-driver as desired, during operation.

Medical Progress.

RECENT PROGRESS IN LARYNGOLOGY.

BY A. COOLIDGE, M.D., BOSTON,

AND

D. C. GREENE, M.D., BOSTON.

TRANSPLANTATION OF BONE IN THE CORRECTION OF NASAL DEFORMITIES.

Carter[1] has successfully transplanted bone from a rib to make up the deficiency in cases of external nasal deformity with absence of bony structures as well as soft tissues. He resects a piece of the right ninth rib about three inches in length, splits it and scrapes away the cancellous tissue from the outer half, then transplants this half between the superficial and deep fasciae over the biceps of the left arm. At the end of ten days the bone becomes incorporated in the tissues, and a flap about one-third larger than is needed to reconstruct the nose, is dissected up. This flap includes the bone graft and is made large in order to allow for contraction which always takes place. The upper end of the flap is sutured into proper position on the face, the end of the bone graft being placed under the

periosteum over the naso-frontal process. The lower end of the flap remains attached to the arm which is bound to the head by means of plaster strips and bandages. Three days later, skin grafts are removed from the thigh and placed on the under surface of the flap. Union between the flap and the face becomes complete in about two weeks after the operation, and the attachment to the arm is then severed. The circulation in the flap immediately becomes feeble, and there is apparent danger of necrosis. Carter believes that this condition can be partially relieved by attachment of a leech to the distal end of the flap, the suction of the leech producing a strong flow of blood through the recently formed capillaries at the connection of the flap with the face. Subsequent minor operations are necessary to mold and shape the flap into the desired form.

A similar method is recommended by McWilliams[2] who, following the procedure of Finney and McGraw, uses the left ring finger. The skin from the whole circumference of the last phalanx is removed, and the tip of the phalanx is nipped off with a rongeur. The metacarpo-phalangeal articulation is opened, the head of the metacarpal bone is removed and the tendons and ligaments about the joint divided. The finger is then slipped into place, the extremity of the last phalanx going up to the frontal bone under a bridge of undivided soft parts which have been elevated by knife dissection. Immobilization of the head and hand is accomplished by plaster of Paris bandages, including left arm, body, neck and head. In three weeks the finger is amputated through the metacarpo-phalangeal articulation. Eight days later, the first phalanx is flexed to a right angle relative to the second phalanx, and its tip sutured into position. More or less sepsis is apparently inevitable, but the infection is not severe and healing takes place with only moderate delay.

VACCINE THERAPY OF NASAL DISEASES.

During the past few years a large number of practicing physicians have been treating their patients with vaccines to combat some definite or indefinite infection. Among these infections are included the acute inflammations of the upper respiratory tract commonly called "colds," and also more chronic conditions of the nose and accessory cavities. For various reasons practitioners have tended to divide into two groups, those who use vaccines frequently and those who use them very infrequently or not at all. Under such circumstances it is reasonable to suspect that both of these groups are extremists, and that the time is ripe for a better understanding of the limitations and the benefits of this form of treatment. A committee appointed by the Council on Pharmacy and Chemistry of the American Medical Association has prepared a series of articles dealing with the whole subject of bacterial vaccine therapy, from which a few quotations briefly describe existing conditions.*

Formerly the autogenous bacterial vaccines were cautiously administered by the expert bacteriotherapeutist, now any physician is supposed to be competent to inoculate patients with all sorts of commercial vaccines. In little more than half a decade a method of biologic treatment of unusual intricacy, the value and limitations of which are still far from being accurately determined, has gone into the hands of the medical profession as a whole. In the midst of this chaotic situation the prudent and thoughtful physician finds himself sorely perplexed. He who would use and not abuse bacterial vaccine therapy has no unprejudiced guide as to its administration, value and limitations.

That the popularity of clinical vaccine therapy has far exceeded its scientific aspects is clearly shown by the still prevailing uncertainty which exists in the minds of many relative to the exact nature of serum and vaccine therapy. Vaccine therapy is a method of producing an active immunity by the injection of bacteria or their products directly into the patient. The active agent is the bacterial vaccine, which is actually a suspension of bacteria in water or in normal salt solution.

Theoretically, autogenous vaccines are the agents par excellence of vaccine therapy. By their use antibodies of precise specificity are aroused and specificity is found to be a predominating characteristic of antibodies as further progress is made in their study. Autogenous vaccine therapy makes prerequisite a bacteriological diagnosis, the only really scientific method of approaching the treatment of an infection.

Bacterial vaccines were originally used only in chronic and subacute infections, and theoretically this limitation is justified, but improvement of both local and general conditions following the inoculation of a correctly graduated dose of autogenous vaccine in acute cellulitis and phlegmon has been observed and recorded by a sufficient number of competent workers to justify its further trial.

As material for his experiments in vaccine therapy the practitioner who relies on the market products should supply himself with vaccines of individual bacterial species. He should learn to discriminate cases in which stock vaccines can be successfully used, and procure a stock representing this selection.

For use under circumstances in which autogenous vaccines are not available staphylococcus vaccine is prominent among the comparatively few which by common consent are valuable as stock preparations. In the literature advertising commercial vaccines, staphylococcus vaccine is recommended in otitis media, mixed infections, mastoid infection, frontal sinus and an-

* The committee consisted of Drs. Ludvig Hektoen, Chicago; David L. Edsall, Boston; John Howland, Baltimore; Reid Hunt, Washington, D. C.; and Albert P. Ohlmacher, Detroit.
The first article appears in the *Journal of the American Medical Association*, April 26, 1913, p. 1298.

trum of Highmore infection. Such a list embraces both localized and general infections of variable etiology with staphylococci as exceptional factors, or if involved usually secondarily.

The field of usefulness of the stock streptococcus vaccine is strictly limited, and this limitation seems to be directly related to the variations which streptococci from different sources and different morbid conditions present which lead to the appearance of those diverse biologic characteristics by which they are differentiated into the groups, races, or strains which subdivide the pathogenic streptococci as a species.

In such affections as streptococcus angina and adenitis following milk infection, autogenous vaccine therapy has been advocated.

The organisms included under the species pneumococcus vary as to races, strains or groups much as streptococci. For specific therapeutic effects one must recognize this variation to the extent of providing for autogenous vaccines in such cases as offer promise for bacterial inoculations. There is little evidence that stock or autogenous vaccines are of value in pneumococcic infection.

The committee concludes that vaccine therapy is a highly specialized field of medicine whose successful pursuit calls for a particular training in bacteriology, immunology and clinical medicine. The therapeutic possibilities of vaccine therapy have been exaggerated. The promiscuous use of the stock bacterial vaccines of commerce in the treatment of acute and chronic infections is an irrational procedure. Ready mixed commercial vaccines should be abolished. In cases suitable for bacterial therapy, autogenous vaccines are with few exceptions superior.

DIPHTHERIA CARRIERS.

Cases which continue to show positive cultures for diphtheria for weeks after the disease has clinically disappeared frequently worry the boards of health and are the despair of the attending physician. The bacilli reappear after vigorous local antiseptics. Cases have been reported in which removal of the tonsils and adenoids has been followed by prompt disappearance of positive cultures, but this rather radical treatment has not always been successful. Vaccine therapy with Klebs-Loeffler vaccine is also of doubtful value. Recently Schiotz[3] has sprayed cultures of staphylococci into the throats of diphtheria carriers and obtained a quick disappearance of the diphtheria bacilli with no bad results to the patients. Similar results have been reported by others, although in one case[4] the use of the staphylococcic spray was followed by an attack of acute tonsillitis with abundant staphylococcus growth.

Wood[5], suggests the use of a spray of Bacillus Acidi Lactici. He has used it in five cases with good results after failure with local antiseptics.

On the other hand, Bissell[6] concludes from work done by the Buffalo Department of Health, that these cultures do not destroy the bacilli of diphtheria, but merely make their detection impossible.

REMOTE RESULTS OF TONSILLOTOMY AND TONSILLECTOMY.

In a comparative study of 110 cases of tonsillotomy in Harmer's clinic and an equal number of cases of tonsillectomy, with reference to the remote effects of operation, Whale[6] finds that with the single exception of voice troubles tonsillectomy is more likely to cure the complaint for which advice is sought. Impairment of the voice or failure to improve vocal disturbances was noted in 27% of the tonsillotomy cases and in 48% after tonsillectomy. It is to be remembered in determining the value of such statistics as these that standards of voice production differ with individual observers. That a change in the quality of the voice corresponding more or less to the amount of tissue removed, may take place, is to be expected, and in view of this fact, due caution should be exercised in recommending professional singers and speakers for tonsil operation.

SUSPENSION LARYNGOSCOPY.

The direct method of inspection of the larynx has long since established its value in connection with operative procedures in the larynx, trachea and bronchi. An interesting and promising adjunct to the method has been devised by Killian[7] in an apparatus for suspension laryngoscopy. The object of the apparatus is to enable the operator, after placing his laryngeal speculum in the position giving the proper view of the larynx, to fix it in that position by mechanical means so that both his hands may be available for the operative purpose. Its function is that ordinarily performed by the assistant who holds a retractor in a general surgical operation, but in this case it does the work better than an assistant because here an assistant is unable to tell whether his retraction is effective or not since he cannot see the laryngeal region which is only visible to the operator. An assistant's retraction is therefore ineffective and it is necessary either for the operator to do his retracting himself, thus leaving only one hand available for operating, or to use some mechanical device which will hold the speculum and the head of the patient in the desired position.

Killian's apparatus reduced to its simplest terms consists of two parts:—(1) a right angled laryngeal speculum having a hook at the end of the handle, and (2) a gallows on which the speculum is hung by the hook. The gallows is adjustable in all directions.

The patient being placed in the dorsal position on the operating table with his head and neck extending beyond the end of the table, the laryngeal speculum is introduced in the usual manner until a good view of the larynx is ob-

tained. The speculum is then held in this position by attaching it by its hook to the gallows which is adjusted to the proper position. The weight of the patient's hanging head is thus chiefly supported by the apparatus at its point of pressure at the base of the tongue.

It is admitted by Killian that suspension laryngoscopy has its limitations. Patients whose mouths cannot be opened wide, those who have long projecting upper teeth, and those with thick, resisting tongues, present, in some instances, great difficulty in the use of the apparatus. It has been used and favorably reported on in this country by Freudenthal[8] and Mayer[9].

Albrecht[10] has made an alteration in the speculum with a view to securing a better view of the anterior commissure.

CHRONIC STENOSIS OF THE LARYNX AND TRACHEA.

Lynah[11], in an interesting study of chronic laryngeal stenosis confined principally to stenosis following diphtheria, gives a general résumé of the pathology. He considers that all of the pathological lesions met with in the various forms of chronic stenosis, whether the primary cause be diphtheria, syphilis, or what not, follow the same course of new connective tissue, cartilaginous, and bony development.

In laryngeal diphtheria the basis for the whole of the pathology of the condition is laid down in the beginning with the acute diphtheritic exudate and primary intubation. When the exudate resolves early the patient is able to remain without the tube on the first extubation, but when the exudate does not resolve early and extubation is performed the subglottic infiltration necessitates the wearing of a tube for a longer period. The tube virtually acting as a foreign body, causes pressure on the swollen laryngeal soft parts, and as it rides up and down or antero-posteriorly during the acts of coughing and swallowing, the unhealed ulcerations are increased, which also add to the necessity of prolonged intubation. These pressure ulcerations are most marked at the cricoid cartilage, and when of sufficient degree cause necrosis with absorption of the whole of the cricoid ring, with the frightful sequelae of persistent auto-extubation. With the absorption of the cricoid cartilage the tube can no longer be held in place by the retention swell, and is, therefore, auto-extubated, and as the tube is coughed out the larynx collapses, or the walls are sucked together by the first inspiration of the patient.

The necrosis is the starting point of the subacute and chronic cases. Round cell infiltration, followed by productive inflammation, which leads to the formation of new connective tissue, altogether reconstructive, obliterates the lumen. This new connective tissue is richly supplied with blood vessels. Now the changes next involve the cartilage, and the regeneration of the thin areas left results in ossification, and where we once had a cartilaginous cricoid we now have new bone formation.

In treatment, gradual dilatation with special tubes measured in millimeters with increasing diameters, is advised. The tubes should dilate antero-posteriorly as well as laterally, and tubes of cigar shape accomplish this purpose. They are gradually increased in size until the largest possible dilatation is accomplished, and are changed once each week for the purpose of cleansing, a size one millimeter larger being introduced at each change.

LARYNGECTOMY FOR CANCER.

In no department has progress been more marked than in external operations on the larynx. During the past year two notable contributions on this subject have been made by Crile[12] and Gluck[13]. The former in a series of twenty four cases reports an operative mortality of two while the latter has had no deaths in the last sixty-three cases operated upon by him. In striking contrast with these figures are those of Sendziak published in 1888. In 147 cases of laryngectomy reported at that time there was an operative mortality of 39%. The cause of death in by far the largest number was inhalation pneumonia; next came sepsis about the larynx or trachea; other and less frequent causes of death were secondary hemorrhage and shock. It is evident that the improvement in results in the series now reported is to be traced directly to improved technic based upon a study of the causes of death above mentioned and of the most effective methods of combating them. Gluck maintains that inhalation pneumonia and sepsis can be avoided by what he considers the essential step of his operation, namely the complete segregation of the trachea from the laryngeal wound. The order of his operation is as follows:—

1. Dissection of larynx and trachea and ligature of vessels before opening the air passage.
2. After separating the larynx from the pharynx, closure of the pharyngeal opening.
3. After separation of the larynx from the trachea, suture of the latter to the skin.
4. Closure of the entire wound by suture except for iodoform gauze drainage at the upper and lower limits of the wound.

Crile's[14] technic differs in some essentials from Gluck's. He considers the dangers from the operation to be: 1. Inhalation pneumonia. 2. Local infection. 3. Mediastinal abscess. 4. Vagitis. 5. Shock and collapse due to injury of the laryngeal nerves. The first danger is avoided by scrupulous maintenance of a dry field in the entire course of the preliminary dissection, and control of the bleeding in the later stages by posture or the use of novocain and adrenalin, preference being given to the latter. The second danger is combated by attention to foci of infection in the mouth and throat, by

careful sharp dissection and by the use of iodoform gauze packing. The occurrence of mediastinal abscess is avoided by preliminary tracheotomy and at this operation packing of the lateral planes of the neck with iodoform gauze. By this means a barrier to infection is produced in the form of a wall of granulation tissue. The danger of vagitis caused by trauma to both pneumogastric nerves is a real one. It is serious only if both nerves are simultaneously injured. Therefore at the preliminary operation it is advised to carry the dissection along side of the larynx on one side all the way to the upper margin of the field of operation and then pack this territory with iodoform gauze, and so let one vagus take the brunt of exposure and adjustment before the larynx is removed. By the time the laryngectomy is done the first vagus would be likely to resume its function, should it have been affected, or at any rate the heavy onslaught of the vagi simultaneously is avoided.

The hypodermic injection of atropin 1-100 grain with the local application of novocain is a protection against the danger of shock and collapse.

Crile advises against freeing the trachea and stitching it to the skin on account of the danger of necrosis of the stump, cutting out of the stitches and consequent retraction of the trachea into the thoracic cavity.

Reports of Societies.

MIDDLESEX EAST DISTRICT MEDICAL SOCIETY.

The regular meeting was held at the American House, Boston, Nov. 19, 1913. Dinner was served at 6.30 p. m., President, DR. WILLIAM H. KELEHER presiding; Dr. A. E. SMALL, Secretary.

Dr. L. R. G. Crandon of Boston, read the paper of the evening on

SURGICAL DRESSINGS.

He said in part that the topic is timely inasmuch as our attitude toward the treatment of wounds is approaching a more rational and reasonable basis. A beginning infection is local first, then more and more diffuse. To combat it we must get more blood to the part. We get arterial blood by means of heat and moisture in the form of the old-fashioned poultices; and venous blood by Bier's hyperemia. An increased amount of blood in the part kills the infection, it remains localized and we can then drain. The right cut for a septic process is a delicate matter. The active process is a core with a wall round about. A big cut through this protecting wall is the worst possible thing. The incision should be made into the centre and only large enough to let the pus out. "Drains" do not drain. We must have something to keep the drainage going. This is accomplished by Wright's solution, where action is based on the principle of osmosis with the additional benefit of dissolving the blood clot, etc., thus preventing the plugging of the opening. The dressing is put on hot and sopping wet and kept so for 24 to 36 hours. If kept in longer the wound becomes macerated and soggy and loses its power of healing. No wick is put in and the wound remains wide open. Thus the acme is past when the incision is made. We have dropped the use of most of the chemicals. Corrosive sublimate has absolutely gone by. It forms an albuminate and keeps the wound hot and uncomfortable. With regard to sulpho naphthol, certain bacteria seem to prefer it to anything else as a culture medium. Chlorinated soda has some virtue in that it sets free one atom of nascent chlorium and so helps combat the infection. A watery solution of myrrh is good in the convalescent stage, as it is stimulating, pleasant and comfortable. After Wright's solution it is desirable to use something soft and emollient. This is obtained by balsam Peru, a drachm to the ounce of castor oil. Also glycerine which is slightly antiseptic and at the same time dehydrates. Mild chemicals such as boric acid, eucalyptol 5% in vasaline base may also be used. Scarlet red probably does not cause much spread of epithelium.

Boils may have a general significance, but when there is a crop close together it is a reproach upon the doctor. To treat them, smear the surrounding skin with boric acid ointment, and powder the top with boric powder. It takes a week to ten days for one to mature, and everything is ready when it opens. Never incise, but wait.

Carbuncle. Staphylococcus vaccine may abort one-fourth to one-third of the cases if seen early. In the late stages, as usually seen by the surgeon, we must excise, cutting deep and removing all the infected tissue. Then apply emollient dressings.

Burns need to be covered with something anesthetic, antiseptic and wet. A saturated solution of picric acid answers all these requirements. Best applied with a thick absorbent cotton dressing and kept wet.

Appendiceal abscess is no longer washed out, but carefully wiped dry so as not to carry infectious material. A spiral cut drain is better for sucking out material and protects the gauze. After once placing leave the wick alone for five days. The cause of the abscess has been removed and all the pus gotten out. There will be no more unless necrotic areas present. The wick is to render the region external to the rest of the body by causing adhesions and making one big cavity. On the fifth day the wick comes out easily and leaves a unit cavity. If removed earlier the intestines are liable to collapse, leaving a lobe deep in, which may cause a secondary abscess. After the wick is removed, pour in balsam Peru and let alone. The same principles hold for any pelvic abscess.

Tuberculous nodes of the neck if localized and freely movable can be excised without cutting into

the gland. Remove the tonsil also. If the node has broken down, we cannot dissect without breaking into it. Make a small incision to let out the pus and then we have to deal with a cavity wall which is alive with germs. The curette is a criminal instrument: it plows up the field and carries germs far and wide, causing a serious spread of the disease. One may wipe out the cavity with gauze, then paint the inside of the cavity with iodine.

The preparation of the field of operation goes through stages of fashion. The iodine preparation is a good way. There may be a hundred others. The preparation is done under ether, cleaning first with benzine, then applying the iodine, following with Harrington's solution and lastly alcohol. This prevents any irritation to intestines drawn out upon the skin. The day of soap and water preparation has gone by. There are enough disadvantages to put it in the discard. The soap is not all saponified. The skin is covered with grease under which the germs grow. Besides the patient all through the operation lies in a pool of water and is liable to suffer from shock.

After a brief discussion the meeting adjourned.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

MEETING OF WEDNESDAY, NOVEMBER 12TH, 1913, AT 8.30 P. M.

The President, Dr. Charles A. E. Codman, in the Chair.

THREE CASES OF MYXEDEMA, ONE ASSOCIATED WITH PITUITARY DISEASE; WITH PRESENTATION OF PATIENTS.

DR. WILLIAM HARMAR GOOD, three cases cited: Mr. J. B., married; 58 years; electrician; rapid onset 15 years ago; typical myxedematous infiltration with markedly subnormal activity of all the organs. Leucocyte count 3020; polymorphonuclear 32%. Improved rapidly up to a certain point on three grains daily dessicated thyroid U. S. P. Then on account of tolerance to glucose, sexual atrophy, an x-ray examination showing absence of posterior clinoid processes, and continued subnormal temperature 96.5°, systolic blood pressure 73 to 80 mm., he was given three grains of dessicated pituitary with great improvement.

Mrs. M. M.; 29; married at 15 years; 4 children; typical myxedematous infiltration; subnormal blood pressure; temperature and pulse, amenorrhoea, obstinate constipation, scanty urine, marked depressional delusional insanity, and profound asthenia of mind and body. Rapid return to normal on 2 grains daily U. S. P. thyroid.

Mrs. T. L., 38 years; two children; seven years duration typical myxedematous infiltration, and subnormal activity of all the organs. Five grains of thyroid in four days caused most profound prostration, but great improvement in symptoms. In three months took but 23 grains of dried thyroid with great improvement and then became very intolerant to but smallest doses of thyroid (¼ every four days). At times could take one or two grains daily.

In the three cases one grain of thyroid was given never more frequently than four times daily and often in but fractional daily doses. The dose of four grains given in U. S. P. is very dangerously excessive.

THE TREATMENT OF PNEUMONIAS.

DR. ROBERT N. WILLSON, The very few who make the distinction between lobar or fibrinous pneumonia and that which we may term for sake of accuracy of description, broncho-catarrhal pneumonia, avoid speaking of the "treatment of pneumonia" and never include under the one term conditions as different as darkness from light. It is most important to determine very early which form of involvement is present. The temperature, pulse, and respiration chart usually suffices to make the differentiation. In most respects the treatment of the two conditions is the same. In certain essential points, however, the methods of handling must be as divergent as two opposite-traveling roads. In both forms of pneumonia an abundance of fresh air is an essential. If possible the patient should be placed bodily out of doors, *provided, and only provided the case is of a febrile type of fibrinous pneumonia.* In exceedingly few, if in any such cases, does the temperature curve average as low as 100°F, and the patient cannot "take cold." He must, however, be protected from the discomfort of extreme weather. The patient with broncho-catarrhal pneumonitis needs the fresh air and oxygen as seriously as does he with the fibrinous inflammation and exudate. If supplied in the form of cold air, however, to a body whose poverty in heat and vital energy is already low, death may be the result. I have seen such result from the use of the "cold fresh air treatment for pneumonia" where the distinction was not made between the types of lung involvement. It would be comparatively safe to entrust the decision between the application of cold, or warm, fresh air to the patient. The regulation of the food supply is important in both types of pneumonia. In the fibrinous inflammation, probably the entire seven or nine days might be experienced by a well nourished patient with no food intake with more surely favorable result. For the comfort of the family, at least, food must be administered. It becomes an object, however, to use as little as possible of the most nourishing, and easily digestible form of food, at as infrequent intervals as the exigencies of the case permit. Milk forms the ideal diet so long as tympanites. To this one staple may be added or substituted for it, simple soft foods such as junket, custard, one minute boiled eggs and soft milk toast. In the broncho-catarrhal pneumonias the patient requires from the first a supporting diet, but not more than is needed for the body requirements or can be digested. I have found it helpful to prescribe approximately two quarts of milk in the 24 hours and in addition, three times during the day, a one minute boiled egg and some agreeable addition, such as custard, finely chopped meat, mashed potatoes, lettuce, dry toast, or a little of any simple vegetable desired. This regime cannot be safely followed unless the intestinal canal is kept clean. An adequate supply of drinking water is an essential in the treatment of the pneumonias. Three pints or two quarts should be taken by the average adult patient during the twenty-four hours. A valuable aid to the favorable prognosis in both types of pneumonia is a thorough initial intestinal sweeping by means of castor oil repeated every second day throughout the course of the disease. Under

this regime, provided a sufficient supply of clean fresh air of the proper temperature be afforded, the vast majority of patients will require no other drug treatment from start to finish. Of the non-medicinal measures the care of the skin is one of the most important. Serous collections should be removed as soon as recognized. Every measure of treatment which interferes with the patient's rest of mind and body should be interdicted and the patient should have an interval of rest of at least three hours. After the initial intestinal housecleaning drugs should not be administered without definite indication. Aconite which in fibrinous pneumonia will quiet the over-acting heart, in broncho-catarrhal pneumonia is not safe. Alcohol is a cardiac muscle poison and a vasomotor paralyzant. "Purging, diet and bathing" were the watchwords of Aesklepiades and of a long succession of the Ancients. Add both cold and warm fresh air to this triad, and we have the outline of the most successful modern treatment of one of the most treacherous and dread forms of systemic and pulmonary disease.

DISCUSSION.

DR. S. SOLIS COHEN. Dr. Willson's division of the pneumonias into acute, lobar, croupous, catarrhal or inflammatory catarrhal is not quite complete, because the broncho- or catarrhal pneumonia must be subdivided according to the causative organisms. The treatment that would be suitable to a case of tuberculous broncho-pneumonia would be unsuitable to a case of influenza broncho-pneumonia. From a study of the statistics it is found that the average mortality of pneumonia in the last thirty years is in the neighborhood of 33%. Previous to the last thirty years it was about 25%. The measures used by our fathers were rather vigorous,—venesection and heavy doses of various drugs. The expectant treatment has not been as successful as even the misguided treatment of an earlier period. The one greatest advance of modern treatment is the exposure of the patient to fresh cold air. Excluding the sort of cases that come to the Philadelphia Hospital, having been exposed to all sorts of weather and with pathological conditions in the various organs, the mortality should be reduced to 20%. I believe we can do still better by the proper administration of quinine and other indicated measures.

SOME REMARKS ON A PHASE OF THE COCAINE EVIL IN PHILADELPHIA.

DR. J. NORMAN HENRY: Two cases are cited of young men seventeen years of age who acquired the habit of using cocaine by obtaining the drug in the streets of Philadelphia. My object in presenting the matter is to call attention to the accessibility of the drug; also to the fact that there is an effort made by the authorities to prevent its sale and to say that if our cases are reported to the Department of Public Safety measures will be taken to trace the selling of cocaine, secure evidence and the conviction of the sellers.

EXPERIENCES FROM A NINE YEARS' SERVICE IN SEVERANCE HOSPITAL, SEOUL, KOREA.

DR. J. W. HIRST: It is about thirty years since the first foreign doctor went into Korea. The city of Seoul with a quarter million of people knew nothing of surgery until 1888. It so happened that an American surgeon at that time was able to serve one of the members of the royal household. Twenty years later a hospital was established which was the first building in that country in which it was possible to accept patients and attempt to treat them. These are the conditions under which it was my privilege to enter nine years ago. The first operation ever done in the Seoul Hospital was for cataract. Facial blemishes the result of inflammatory diseases are frequent. I also have seen many cases the result of smallpox which in earlier days was so prevalent there. Today under vaccination there is a generation which does not know the disease. I have seen the largest series of empyemas in our service that I have ever read of anywhere else. Why it should be that empyemas are so prevalent I am not able to determine. Pneumonia is just about as prevalent in Korea as in this country. Appendicitis is almost unknown. The people are a rice-eating people and as a rule are not so subject to constipation as people in this country. They also are a people who do not chew their food. Typhoid fever is not very prevalent, but typhus fever becomes a great scourge.

There are some fevers which do not show the same characteristics as the conditions laid down in our text-books. The people in their acceptance of surgical aid in the first instance were afraid of a foreigner, but gradually a change has come. Not long ago we had two women living in the same room one of whom had ascites and the other a large abdominal tumor. The woman with the tumor was operated on and the other woman demanded that she also be operated on. So that the leaven is leavening the whole lump and one patient satisfactorily treated in a community will affect a large number. The Chinese practice of surgery is a series of needles, long and short, hot and cold and sometimes they are twisted like a small corkscrew, also triangularly. I removed a fibroid uterus the size of a child's head which had been treated by a native surgeon by passing needles through the abdominal wall and three needles were imbedded in it when removed. We have records of other cases in which a mass was removed from the body containing needles which had been forced into the tumor. The native doctors never attend labor cases. These were always in the hands of the old mothers in the homes. Prolapse of the uterus was treated by the insertion of a pledget of cotton soaked in alcohol. This was set on fire and the parts would be so badly burned that the uterus was held in place by contraction.

THE AMERICAN NEUROLOGICAL ASSOCIATION.

THIRTY-NINTH ANNUAL MEETING, HELD AT WASHINGTON, D.C.

MAY 5—7, 1913.

THE PRESIDENT, DR. PEARCE BAILEY, NEW YORK, IN THE CHAIR.

(*Continued from page* 23.)

LESIONS OF THE HYPOPHYSIS AND OF THE UNCINATE REGION, WITH THE RECORD, CLINICAL AND PATHOLOGICAL, OF A SERIES OF CASES.

DR. CHARLES K. MILLS AND WILLIAMS B. CADWALADER, Philadelphia: The paper is based on a

series of eight cases, two of which had been previously shown at another society, both before operation. Of the eight cases, one had presented uncinate without pituitary symptoms, necropsy in this case showing a large tumor involving the uncinate convolution, but extending into other regions of the cortex and subcortex. Of the other seven cases, three presented both pituitary and uncinate phenomena of a decided character. In the other four uncinate symptoms were absent, pituitary phenomena being pronounced. These phenomena, however, were of a mixed character, illustrating dyspituitarism rather than either hypo- or hyperpituitarism. In one of the cases with decided uncinate symptoms no lesion of the temporal lobe was discoverable In one case in which the patient died after operation, a necropsy showed a tumor involving the infundibulum and pineal gland and adjoining structures. In three of the operated cases pathological conditions of the hypophysis were found at the operation and confirmed by microscopical examinations of parts of the tissue removed. The authors are favorable to the fronto-orbital operation of Dr. Frazier for the exposure of the hypophysis. They believe it has distinct advantages over that of approach by the nasal route. Operation, however, gives successful results only in a limited number of cases. The authors of the paper discuss the manner of the production of the conjoint pituitary-uncinate symptom complex.

DR. J. RAMSAY HUNT, New York: Has Dr. Cushing had any cases of complete transitory blindness referred to him? I saw quite recently with Dr. Kinnicutt at the Presbyterian Hospital a case of pituitary disease in which there were no changes in the sella turcica. The man was placed on extract for two or three weeks. He returned to the hospital saying that he had been seized quite suddenly in the engine room, where he was working, with blindness which had lasted for four hours at the time Dr. Ramsey saw him. It seems that the blindness had something to do with the acromegalic signs.

DR. HARVEY CUSHING, Boston: In reply to Dr. Hunt's query, I would say that I have seen many cases of scotomata and these scotomata, as de Schweinitz has pointed out, are very apt to occur in the upper, outer quadrant. They are largely due to the fact that there is apt to be fluctuation of these symptoms. The gland swells against the chiasm which accounts for the loss of vision in the upper and outer quadrant. In cases which have passed beyond the stage to be cured by operation I would limit myself to a minor measure such as the mere relief of pressure rather than a large major operation such as the exposure of these structures through the frontal region. Such a lesion as a cyst is, of course, easily approached from below. The duration of the stay of the patient in the hospital from operation by the trans-sphenoidal route is comparatively a few days. It is not much more than a submucous resection of the septum, which the laryngologist not infrequently practices in the out-patient department. There have been 104 patients in my series and there have been 75 surgical cases. In 46 of the 75 there has been the trans-sphenoidal operation; in 22 subtemporal decompressions and 8 have had trans-sphenoidal and temporal decompressions. So that there have been 93 operations. There have been 9 fatalities, about 10%. Most of these fatalities occurred in the early series. Thus of these fatalities most of them were cases which today we would recognize as inoperable or would adopt a simple measure. Two of them were simple subtemporal decompressions with very large tumors. I think the operation merely takes part of the growth. It is inconceivable that one can remove the entire growth. If the growth is accessible from below I think it should be approached from below. What we want to do is to make room for enlargement of the growth. We cannot remove it entirely. I feel that this measure to which Dr. Frazier has again called attention, and which was first advocated by Hartley and subsequently by Krause, is in Dr. Frazier's skilful hands a measure that very likely can often do good, but it is one which I should feel very badly to have come into general use.

HUNTINGTON'S CHOREA: A STUDY IN HEREDITY.

DRS. SMITH ELY JELLIFF, ELIZABETH B. MUNCEY, and C. B. DAVENPORT, New York: In the last ten or twelve years we have been able to get together enough information to show that one could group these cases of Huntington's chorea into four large groups. For the last four years Dr. Munsey has spent all the time working on this material, with the result that practically all of the old family Huntington chorea in this country has come from five distinct families. The names of these families are now fairly well known. It has taken thirteen years to collect the material, and it will take five or ten years more to present complete analyses of what the material shows us. At the present time it confirms the statement frequently made that Huntington's chorea does not skip a generation. If any individual is free from the disease that individual's offspring will be free. Once the line of descent is free, always free. If one individual does not have the disease it means that he does not have it in his germ cells and hence cannot transmit it. The practical application of this rule to eugenics is diminished by the fact that Huntington's chorea does not come on until late in life. As to marrying, each member feels that he may escape and if he considers the matter at all runs the chance. In a person whose onset is relatively late in life it is to be expected that the parents will often die before the disease is due to develop in them. In certain of the families one will find the cropping out of the Huntington chorea, nothing in the antecedent heredity and later it turns out that there was illegitimacy, so that occasionally comes into these charts to explain the law of Mendelian dominance.

THE VALUE OF X-RAY ANALYSIS OF THE GASTRO-INTESTINAL TRACT IN SOME TYPES OF SO-CALLED FUNCTIONAL NERVOUS DISORDERS.

DR. L. PIERCE CLARK and DR. ARCHIBALD H. BUSBY, New York: In a careful and complete x-ray analysis of eight cases of idiopathic epilepsy associated with severe gastro-intestinal disorder the authors found some form of abnormal position of the viscera (ptosis) which they judged to be pathological in each case and which they connected up with some of the clinical symptoms in the individual case. They outlined a system of physical therapeutics to overcome the gastro-intestinal ptosis which had been of functional benefit. They advised a routine x-ray examination in every case of genuine epilepsy with severe indigestion as an aid in exact diagnosis and treatment of the indigestion and the convulsive disorder itself.

DISCUSSION.

DR. D. J. MCCARTHY, Philadelphia: I can support what Dr. Clark has said in his paper from an extensive study of the past year on not only this group of cases but the entire group of functional cases that come to the neurologist's office. Wherever there has been suspicion of gastro-intestinal involvement, I have had x-ray tests made. The percentage of cases of what has been considered the functional neuroses in which one gets lesions, not only equal to those shown in Dr. Clark's group of cases, but even more intense, is surprising. Among those cases operated on, where they have been well selected, uniformly excellent results have been obtained.

DR. HERMAN H. HOPPE, Cincinnati: I believe that, while the study of this condition is very interesting, before the profession can come to any conclusion as to the therapeutic results a larger number of cases must be studied. There is, on the part of a great many patients an objection to having an operation of a serious character done for a primary condition that has existed for a long time. Some practitioners have found the straight front corset to answer nearly all purposes. One case of epilepsy occurs to me as presenting complete recovery following operation.

DR. J. W. MCCONNELL, Philadelphia: I am not interested in the surgical side of these cases, believing, as I do, that the matter of internal therapeutics has not been sufficiently worked out. There is too much tendency to go ahead and carve up these patients. For several years I have been working very carefully at the condition of displacement of the abdominal organs with direct reference to their effect upon the nervous system and incidentally upon the general digestion. In the matter of treatment of these cases I have largely been depending upon abdominal supports made of very heavy adhesive plaster. Up to the present time I have had certainly 300 or more cases in which there has been very distinct relief of the gastro-intestinal symptoms and a very definite improvement to the peculiar toxic condition which those patients naturally get into.

DR. C. A. L. REED, Cincinnati: Having had a number of these cases referred to me, notably by Dr. Hoppe and Dr. Langdon, I have had some very satisfactory results following surgical restoration of these displacements. It is no more possible to reduce these displacements by medicines than it is to reduce a dislocated elbow with a dose of pills. I have not infrequently applied bandages, trusses and so on with benefit, temporary or partial. But that that treatment can by any possibility restore the patient to normal condition is something not for a moment believable.

DR. EDWARD B. ANGELL of Rochester, N. Y., said that as soon as you have corrected the intestinal fermentation that distends the bowel and causes the pressure, permanent relief will be afforded the patient. He has many times had the pleasure of taking off the supports and leaving the patient much more comfortable.

THE INTERPRETATION OF DIFFERENCES IN MAMMALIAN BRAIN WEIGHT IN TERMS OF THE STRUCTURAL ELEMENTS.

DR. HENRY H. DONALDSON, Philadelphia, Pa.: Among different species of mammals of increasing size and increasing brain weight, present information justifies the general conclusion that the larger brains are composed of the greater number of structural elements.

Within a given species, however, the question arises whether the number of elements in the large brain is really greater than in the small brain, or whether we are to regard the large brain as composed of the same number of structural elements as the small brain—the size of the elements accounting for the difference in gross size.

In man we find differences of 10 to 20% in the brain weights among the two sexes and at different ages after maturity. There is about the same range of difference in brain weight in the rat—the brain of the very large wild Norway being about 20% heavier than that of the corresponding domesticated albino.

Using the rat as the species for study, the following relations have been found: The brain weight is alike in the two forms (wild Norway and albino) during the first three weeks of life. The relative weights of the divisions of the brain are alike in the two forms, despite the difference in absolute weight. The percentages of water in the several subdivisions are similar in both forms. The observed number of medullated fibres in one peripheral nerve (nervus peroneus) is the same in both forms. The size of the cell bodies in several localities is found to be greater in the Norway than the albino. Finally, as the weight of the brain is closely correlated with the body size, it is possible to produce from the same litter, by modification of diet, animals with brains of different absolute sizes. These brains presumptively contain the same number of neurones.

All this points to the general conclusion that in the case of the rat the differences in the size of the brain are due to differences in the size of the elements.

If we apply these tests to man, we find that so far as the observations exist the results are similar.

It is concluded, therefore, that within a given species of mammals—illustrated by man and the rat—the difference in the absolute weight of the brain either within the same sex, or when the two sexes are compared, is mainly due to differences in the size of the constituent elements.

DISCUSSION.

DR. E. E. SOUTHARD, Boston: As to the question of agenesia versus aplasia connected with the dementia precox brains which I have been studying, I find that the various persons with whom I have talked felt that, for instance, in a small brain in dementia precox patients there might well be agenesia. If these conclusions of Dr. Donaldson be correct, it might be that the small brain of dementia precox, like the small heart or small aorta, is an instance of aplasia or hypoplasia rather than agenesia. Agenesia should mean a condition in which certain elements are lacking; while aplasia should mean an alteration in the negative direction, in the size or other qualities of the cells. There are no gradations in respect to agenesia; it is either genesis or agenensis. We should be careful how we speak of the brains as examples of agenesia. If we get used to employing the word agenesia, we will come to think that dementia precox means an absence of certain elements; whereas, it may not at all mean such. In fact, the evidence would seem to the speaker to be rather that the dementia precox brains are in pos-

session, perhaps, of their normal quantity of elements. Many counts would have to be made to make this point good.

DR. HENRY H. DONALDSON, Philadelphia: I have recently been over a short series of brains belonging to deficient and defective children from the Vineland, N. J., institution, and, separating them into their larger divisions of cerebral hemisphere involvement, etc., and taking the weights of these, I was rather surprised to find that the weight relations were those of the normal brains, in most cases. My own interpretation, in fact, is in favor of the view that the elements composing these brains are small in size, rather than deficient in number.

EXPERIMENTAL STUDY OF INTRANEURAL INJECTIONS OF ALCOHOL.

DR. ALFRED GORDON, of Philadelphia: The experiments were carried out on dogs with the object of determining the effect of alcohol on motor and sensory or mixed nerves. The facial infraorbital and sciatic nerves were exposed by dissection during anesthetization with chloroform and 5 minims of 80% alcohol were injected. The first series of dogs were kept alive nine days, the second series twenty-nine days. Not only the peripheral nerve-trunks, but also the nuclei (Gasserian and spinal) were examined microscopically. The facial nerve was traced through its course in the medulla. The histological and clinical findings were then given in detail. The conclusion to which I have arrived is, that while very little or no damage is done to a motor nerve, the sensory and mixed nerves present very little resistance to the effect of alcohol. Irreparable damage may be done in the latter case, but in the case of motor nerves restoration of function was almost the rule. Illustrations of the histological findings were appended.

DR. ISRAEL STRAUSS, of New York: I can in a way bear witness in confirmation of the author's results. Two years ago I saw a patient into whose sciatic nerve there had been an injection of alcohol, the result of which injection was a complete paralysis of the muscles of the leg. This paralysis lasted over one year; and, in addition to said paralysis, there developed trophic ulcers upon the foot, also a marked edema. There was at the end of a year, almost no sign of restoration of the power of those muscles and the trophic ulcers, while they would heal, would appear in new regions. It was his opinion that probably the trophic condition of the foot put that patient in such jeopardy that amputation might eventually be necessary.

DR. EDWARD B. ANGELL, Rochester, N. Y.: I would inquire whether Dr. Gordon had examined the sciatic nerve after the injection of a saline, rather than alcohol. This would be rather interesting because such injections are now made by men who are using injections for the relief of neuralgias.

DR. PETER BASSOE, Chicago: I consider it my painful duty to tell about an experience I had with an injection in a case of sciatica, not with alcohol, but with salt solution, a method which I have used a great deal, and which I am still using. In the summer of 1908 I injected a number of cases at the Cook County Hospital of Chicago; and a number of cases were injected by the internes, both in the speaker's service and in that of his colleagues. There was one typical case of sciatica injected by an interne; and within, say half a minute, or at most within one minute, a complete sciatic paralysis was produced. The needle was introduced through the buttocks rather high up, using the landmarks advised by some French writers and drawing the line from the conjunction of the coccyx and sacrum over to the upper border of the trochanter. The patient was a nervous man; he did not like the feeling of the needle and jumped. Possibly that had something to do with it; but at any rate the paralysis and loss of sensation were instantaneous. I at once examined him and found there was complete paralysis of all the muscles below the knee and loss of all forms of sensation. The man's sciatica was cured and never returned. The patient still had a complete paralysis of those muscles.

DR. ALFRED GORDON, Philadelphia: In reply to Dr. Angell's query regarding my personal experience in injecting saline solution, I have had quite a number of cases that have been relieved, but not cured, by physiological salt solution. I have tried in two cases the injection of plain distilled water and have obtained equal results as with the saline solution. I have never observed such a danger as Dr. Bassoe has mentioned from injecting saline solution into the sciatic nerve.

(To be continued.)

Book Reviews.

Artificial Parthenogenesis and Fertilization. By JACQUES LOEB, member of the Rockefeller Institute for Medical Research. Originally translated from the German by W. O. REDMAN KING, B.A., assistant lecturer in zoölogy at the University of Leeds, England. Supplemented and revised by the author. Chicago, Ill.: The University of Chicago Press. 1913.

This translation of Loeb's book appearing in 1909, entitled *Die chemische Entwicklungserregung des tierschen Eies,* has been amplified and enlarged by the author in consequence of new observations made since its publication. The investigation concerns itself with the possibility of the development of an embryo from an unfertilized egg, and allied questions. The book is a monument of painstaking chemical and physiological research, and possibly paves the way toward an understanding of the fundamental problem of life and its method of production. If the thesis which the author sets himself to prove is finally established, it may well prove the beginning of an entirely new conception of biological problems and lead to a reconstruction of certain very generally accepted postulates. Much, naturally, remains to be done before this result can be attained. In the meantime Loeb has certainly established facts which may no longer be ignored.

THE BOSTON

Medical and Surgical Journal

THURSDAY, JANUARY 8, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

STANDARDIZATION OF HOSPITAL RECORDS.

On another page of the Journal we print the report of the committee on the standardization of hospitals, presented before the recent meeting of the Clinical Congress of Surgeons in Chicago. In addition to sending to every hospital in the United States and Canada a copy of this report, it is the intention of the committee also to send a leaflet illustrating the practical working of the plan and giving various facts regarding its application and usefulness.

Should the simple suggestions in this leaflet be adopted, as we hope they will be, by the great majority of hospitals, we can see the possibility of a very far reaching effect. In a way it marks the beginning of real clinical science, for each operation or each attempt at any other form of curative treatment in any hospital is an experiment. It seems curious that these experiments should not be recorded in most hospitals. Often the facts thus obtained would be of the greatest scientific value. We must record all cases, since it is impossible to predict beforehand just which cases will be most important; we do not know today what may be of essential value tomorrow. The majority of hospitals nowadays have some sort of record system referring to the condition of their cases while in the hospital, but the real test of the value of operations and other forms of clinical treatment often comes after the expiration of years, long after the patient has left the hospital doors. The Massachusetts General Hospital endeavors by a method similar to that suggested in the leaflet, to trace its cases as a routine, and we feel that the adoption of such a system may well be undertaken by other hospitals, so that they will know whether "their product is sound or damaged." Even if it means the expenditure of much money it may be actual economy, since to expend money for poor results is as wasteful as any other form of extravagance.

It seems probable if the hospitals of the United States should take up this system in a uniform way, that it would lead to a more direct method of eliminating some of the modern surgical abuses than will even the formation of the American College of Surgeons. As far as statistics are concerned, the ordinary hospital morbidity report is nearly useless. It would be much better for the statistician to make his own statistics from a series of abstracted cases than by the method now in vogue. For instance, in the usual report, a patient operated on at the same time for two diseases, such as fibroid of the uterus and adenoma of the thyroid, is classed in the statistics under both of these operations. In reality, the risk of the two performed at the same time is not the same as the risk of either one. In these days it is very common for two or three organs to be removed at the same operation, and we think that the exuberant growth of modern surgery is likely soon to make it necessary to compare the statistics of different operators on this basis.

Correspondence regarding the plan should be addressed to Dr. E. A. Codman, chairman of the committee, 227 Beacon Street, Boston.

MEDICAL LEGISLATION. THE REGISTRATION OF DRUG-STORES IN MASSACHUSETTS.

On January 1, 1914, there went into effect throughout this Commonwealth an act, passed by the legislature last year, requiring the registration of all drug-stores in the state. This law was aimed primarily at establishments which, under the name of drug-stores, existed chiefly for the sale of alcoholic liquors. Secondly, it was expected to prove a means of controlling much of the clandestine and illicit sale of alcohol, morphine, cocaine, and other habit-forming drugs which has been surrep-

titiously carried on by some ostensibly legitimate drug-stores.

The registration of pharmacists in Massachusetts has for some time been on an ethical basis in the hands of the State Board of Registration in Pharmacy. This board will now in addition control the registration of all drug-stores, and will have the power at any time to revoke the license of any such establishment found guilty of evading or transgressing the pharmacy statutes of the state. Any store, in which there is not a registered pharmacist or assistant pharmacist, will be forbidden to sell any drug except a few harmless substances enumerated in a specified list. The board will have full power to investigate all cases and inflict fines for all infractions.

In a statement to the public press, the secretary of the State Board of Registration in Pharmacy has said, relative to the new law:—

"It has been requested that the Board of Registration in Pharmacy state what is expected to be gained by the enforced registration of drug stores. In answer to such inquiry, the members of the board say that they expect to have on hand a complete personnel of every drug store in the state on Jan. 1, 1914, and each year thereafter.

"They expect gradually to eliminate all apologies for drug stores created to do a mercantile business seven days in the week when other stores are obliged to close on Sundays.

"They expect to eliminate certain drug stores capitalized by ex-liquor dealers for the purpose of doing an illegal liquor traffic in no-license localities.

"They expect to assist in stopping the illegal sale of narcotics by having the power to refuse a permit to such drug stores as violate the law in this manner.

"The board feels that the enforcement of this law will bring about a better condition of the business of pharmacy throughout the state, and that the public health will be better protected in having skilled pharmacists conduct the business."

There seems every reason to believe that this new measure is a judicious piece of medical legislation, and that its enforcement should do much to raise the standards and prevent abuses of the sale of drugs in Massachusetts.

AN IMPORTANT DISCOVERY.

ON Dec. 27, 1913, Dr. William David Coolidge, of New York, demonstrated, before a meeting of physicians, physicists, and radiographic experts, his new method for the generation, control, and application of Roentgen rays. In brief, his invention consists of a tube in which both anode and cathode are made of tungsten, and by means of which the penetration and dosage of rays may be most accurately gauged. The advantages claimed for it are as follows:—

"(a) The intensity and the penetrating power of the Roentgen rays produced are both under the complete control of the operator, and each can be instantly increased or decreased independently of the other.

"(b) The tube can be operated continuously for hours, with either high or low discharge currents, and as either a hard or a soft tube, without showing an appreciable change in either the intensity or the penetrating power of the resultant radiations.

"(c) It permits of the realization of intense homogeneous primary Roentgen rays of the desired penetrating power."

It seems that this discovery is likely to prove of great importance in the medical use of Roentgen rays, and a more detailed and technical account of it and of Dr. Coolidge's work will be given in a subsequent issue of the JOURNAL.

MEDICAL NOTES.

INCIDENCE OF POLIOMYELITIS IN NOVEMBER.—The weekly report of the United States Public Health Service for Dec. 26, 1913, states that during the preceding month of November, 38 cases of poliomyelitis were reported in Massachusetts, 14 in California, and 13 in Ohio, these being the three states with the highest incidence of the disease. Of the Massachusetts cases, 10 were in Middlesex, and 8 each in Suffolk and Worcester counties respectively.

SUICIDES IN 1913.—Report from Chicago states that the number of suicides in the United States in 1913 was 13,106, as against 12,981 in 1912. Of the suicides in 1913, 8602 were males and 4504 females. Among professional men, the largest number of suicides was 34, among physicians.

TWO CENTENARIANS.—Mrs. Elizabeth Coburn, who died last week at Guys Mills, Pa., is said to have been born in September, 1813.

Lemuel Coffin, an ancient mariner, died last month at Sailors' Snug Harbor, Staten Island,

N. Y., at the supposed age of 101 years, 5 months. He had been an inmate of the institution for 33 years.

RADIUM RESEARCH LABORATORY.—Report from Denver, Colo., states that on Dec. 26 the National Radium Institute secured in that city a site on which will be erected a laboratory for radium research under the direction of the United States Bureau of Mines.

RADIUM DEPOSIT IN PENNSYLVANIA.—Report from Philadelphia on Dec. 27 announces the discovery near Mauch Chunk, Pa., of an extensive deposit of carnotite, a radium-bearing ore. Assayists have stated that this ore contains 2% of uranium oxide, from each ton of which 108 milligrams of radium can be extracted.

LONDON DEATH-RATES IN NOVEMBER.—Statistics recently published show that the total death-rate of London in November, 1913, was only 13.5 per 1000 inhabitants living. Among the several districts and boroughs, the highest rate was 19.5, in Finsbury, a crowded central quarter, and the lowest was 9.1, in Lewisham, a populous southern suburb.

NEW METHODS TO INCREASE FRENCH BIRTH-RATE.—To encourage the raising of children in France, it is proposed to exempt from taxation all families of more than four, and to give each married voter an additional vote for his wife and for each minor child.

A PARISIAN GASTROPAGUS.—Report from Paris on Dec. 25 states that a case of Siamese twins has recently been brought to that city for operative surgical separation. The infants, which are a month old and both females, are joined by a fleshy band between their abdomina.

BOSTON AND NEW ENGLAND.

WORK OF THE BOSTON CHILD HYGIENE DIVISION.—The recently published report of the division of child hygiene of the Boston Board of Health shows that during the past year the city nurses have made 33,392 visits on 18,438 newborn babies. Of these, 14,065 were bottle fed, 2766 were breast fed, and 1607 were fed on both breast and bottle. The report further comments on the cordial relations and coöperation between the board and the 12 milk stations of the Boston Milk and Baby Hygiene Association.

ACTION AGAINST TWO MASSACHUSETTS CITIES.—At the instance of the Massachusetts State Board of Health, a writ of mandamus was issued on Dec. 30 by the Superior Court, directing the city of Gloucester to prepare plans for a hospital for patients with diphtheria, smallpox, tuberculosis, and other diseases dangerous to the public health. Request has been made for a similar writ against the city of Lowell. The building of such hospitals by cities of over 20,000 inhabitants was required by a statute of the year 1910. Gloucester and Lowell have hitherto failed to comply with this requirement, though specially requested by the State Board of Health to do so in 1911 and 1912.

A CENTENARIAN.—Mrs. David C. Chamberlin, who died on Dec. 28 at Melrose, Mass., was born in Lexington, Mass., on Sept. 10, 1813, the eldest of a family of eight children. She was one of the school-children who in 1825 strewed flowers in the path of General Lafayette when he visited Boston, and is said to have been kissed by the general on that occasion. She was married in 1836, but has been a widow since 1884. She is survived by three daughters, one son, three grandchildren, and nine great-grandchildren.

NEW YORK.

PROGRESS IN SANITATION.—In severing his connection, of twenty-six years, with the Department of Health, Dr. H. M. Biggs, general medical officer, addressed a communication to Commissioner Lederle in which he reviews the advances made in sanitation in the city during this period. In the course of it he says: "A complete and remarkable transformation has taken place in the sanitary administration of New York. No one twenty-five years ago could have anticipated the wonderful progress which has been made in preventive medicine. This progress has been possible only through the scientific developments of this period, especially in bacteriology and in the discovery of new curative and protective methods. But the Department of Health of New York City has set the pace, for this and other countries, in the prompt practical application of the new achievements of science and the lessons of experience. I do not believe the citizens of New York fully realize how far in advance of most of the great cities of the world our administration of the health service has been. During frequent visits to

Europe in the last twenty years I have made a careful study of the work of the health authorities in Great Britain, France and Germany, and have been greatly impressed with the fact that they were but slowly, and often very incompletely, adopting the measures which had proved most successful here. This fact has been long recognized in Europe, and the authorities there constantly look to New York for suggestions and directions in new methods in sanitary work. A glance backward over this quarter of a century shows a prompt and complete readjustment of the administration of the department to meet the new and more precise conception of the infectious diseases which the new bacteriology created."

LIFE EXTENSION INSTITUTE.—On Dec. 29 a "Life Extension Institute" was incorporated in New York, for the purpose of prolonging human life by examining periodically the physical condition of insurance policyholders and other individuals, and by disseminating life-saving knowledge. Its president is Mr. E. E. Rittenhouse, of New York. Mr. William H. Taft is chairman of the board of directors, and Dr. William C. Gorgas consultant in sanitation and hygiene. The chairman of the hygiene reference board is Prof. Irving Fisher, of Yale, and among other members of this board are Dr. George H. Simmons, of Chicago; Dr. William J. Mayo, of Rochester, Minn.; Dr. William H. Welch, of Baltimore; and Dr. Harvey W. Wiley.

"The Institute plans to make arrangements not only with life insurance companies, but with schools, industrial establishments, clubs and individuals, as well as to coöperate with hygienic agencies and movements of all kinds, including those connected with the tuberculosis movement, the social hygiene movement, the eugenics movement, the public health departments, federal, state and municipal, and even popular gymnastics and sports. It will establish laboratories in the larger cities for analysis of blood, urine, etc., of the persons examined. Its central office will be at 25 West 45th Street, New York City.

"The Institute is fashioned somewhat after the Model Homes Associations, that is, it will be a philanthropy conducted on a self-supporting basis. It will charge a small fee for its work, and the persons who furnish the capital with which to start this Institute have agreed that two-thirds of any profits which there may be beyond five per cent. on the capital invested will be devoted to extending its public usefulness.

"A striking feature of the scheme is that all concerned are benefited—the insurance, companies, the policyholders, the individuals examined, and the public.

"This newly invented institution is the result of a sentiment which has been growing several years among life insurance companies to reduce their losses from life-waste, just as the fire insurance companies have for a long time striven to reduce their losses from fire-waste.

"The Hygiene Reference Board will aim ultimately to settle scientifically, so far as possible, the many disputed questions of personal hygiene. As yet personal hygiene has been neglected, especially in America, and "how to live" is a debatable question even among experts. The board will secure the coöperation of savants throughout the world to solve such fundamental problems as how best to ventilate our houses and how best to clothe and feed our bodies. In this way it is hoped to steer a scientific course between the Scylla of foolish fads which beguile the unwary and the Charybdis of conventional ways of living, which most of us accept blindly because others have accepted them before us."

8. GRIFFIN, E. A. *Turbinotomy.*

7. Luttinger reports results obtained with vaccine therapy in ten cases of pertussis. The micro-organism used resembled very closely that described by two Germans as the cause of whooping cough. The writer observed a reduction in severity and a shortening in duration of the disease after inoculation. He says that pertussis vaccine should be given in much larger doses and at shorter intervals than are generally recommended. Prophylactic inoculation was apparently completely successful in one of the writer's cases. The dose recommended for this purpose is fifty million. [L. D. C.]

5. Cyriax attacks the subject of croupous pneumonia from the mechanical point of view. He considers reflex contraction of the muscles of respiration the most important cause of respiratory distress in this disease. The effect of these persistent contractions is limitation of respiratory movement with consequent pulmonary congestion, insufficient oxygenation, cardiac strain, etc. The object of manual treatment is to increase respiratory movements by diminishing muscular contraction and inflammation in lung and pleura, and to improve the patient's general condition. The manipulations and exercises recommended are vibrations, active respirations, subdiaphragmatic suction, friction on the posterior spinal and the intercostal nerves, abdominal petrissage. Treatments should be given twice a day, and in bad cases three times, each sitting averaging half an hour. [L. D. C.]

1. Rosenow and Hektoen have found that when virulent pneumococci are suspended in physiologic salt solution the substances on which their resistance to phagocytosis depends pass into solution. The soluble part at a certain stage of autolysis is highly toxic and has little immunizing action, while the insoluble remnants have well marked antigenic properties and practically no toxic effects. The protective value of detoxicated pneumococci has been found to be greater than that of heat killed pneumococci. The authors have, therefore, treated pneumonia patients by subcutaneous injection every day till the temperature fell, with an injection of virulent pneumococci from which the soluble and toxic parts have been removed. The dose has been from ten to twenty billion at a time. The type of case treated has been of the worst, *i.e.* the alcoholic in hospital practice, and yet the mortality has been greatly reduced and the treatment seems of distinct value.

2. Riesman believes that the term "typhoid fever" as commonly used by physicians includes more than one variety of disease, and that only that in which typical serologic and cultural tests are obtained, should be called typhoid fever. To the others the term entericoid fever might be applied, meaning that this type was due to different strains of the paratyphoid group and to others morphologically similar; the source of infection is chiefly food derived from unhealthy animals.

3. Burns has given up the use of morphia and opium in pulmonary hemorrhage because of its depressing effect and danger of subsequent pneumonia, and in its place has substituted purgation by depletion by use of magnesium sulphate. No bad results have followed its immediate use, such as vomiting, and the control of hemorrhage has been marked. [E. H. R.]

14. JOBLING, J. W., AND STROUSE, S. *Studies on Ferment Action. IX. A Note on the Relation Between Lysis and Proteolysis of Pneumonia.*

6. McPhedran comes to the conclusion from his work with fats that there is no support for the theory that toxic hemolysis results from the liberation of hemolytic fatty acids. In certain pathologic conditions associated with hemolysis, he was unable to find on analysis any evidence for the existence of fatty acids more toxic than the common oleic acid which is constantly being set free by hydrolysis from common fat in health.

10. Noguchi and Cohen describe the cultivation from cases of conjunctivitis accompanied by the so-called trachoma bodies inclusions of an organism resembling the various important stages of the tra-

choma bodies. Animal inoculations were not successful.

12. Gillespie studied the viability of the pneumococcus on artificial culture media. He found that it required a smaller number of pneumococci to start a growth on agar than in broth. The explanation does not seem to depend upon chemical differences, but upon physical differences in the two kinds of media. [R. I. L.]

1. Manwaring and Bronfenbrenner found that tubercle bacilli injected into the peritoneal cavities of tuberculous animals rapidly disappear from the peritoneal fluids, while persisting in the peritoneal fluids of normal control animals. This intra-peritoneal lysis seems to be due to specific changes in the fixed peritoneal cells of the tuberculous animal.

2. MacCallum and Vogel have continued their researches on tetany and have brought forward additional experimental evidence tending to show that tetany is closely dependent upon a disturbance of the calcium content of the blood. [R. I. L.]

BULLETIN OF THE JOHNS HOPKINS HOSPITAL.

DECEMBER, 1913.

1. *BARKER, L. F., AND GIBBES, J. H. *On the Treatment of Leukemia with Benzol.*
2. *BOGGS, T. R., AND GUTHRIE, C. G. *Bence-Jones' Proteinuria in Leukemia: A Report of Four Cases: The Effect of Benzol on the Excretion of the Protein.*
3. *KELLY, H. A., AND NEIL, J. C. *Cauterization of "Inoperable" Carcinoma of the Cervix of the Uterus.*

5. *HERWITZ, S. H., AND BLOOMFIELD, A. L. *Tests for the Hepatic Function. Lactose Tolerance as Influenced by the Liver Necrosis of Chloroform Poisoning.*

1. Barker and Gibbs describe in brief the cases of leukemia which have been treated with benzol by various investigators in the past and the results. The writers add one more case to this list, which they report in great detail. It is important to note that there was a positive Wassermann in this case. They emphasize the fact that benzol does possess dangerous toxic properties; second, that its chemical effects are not yet clearly understood; and third, that the greatest care should be exercised in its administration. No patient should be given benzol unless he can be kept under strict observation. The white cells fell in this case from 345,000 Nov. 24, 1912, to 6,800 April, 1913, with a marked improvement in all the symptoms.

2. This paper, as stated in the title, describes in great detail four cases of Bence-Jones' proteinuria.

3. Kelly and Neil believe that the extensive radical operation offers the greatest hope of absolute cure in patients suffering from cancer of the cervix uteri; the percentage of operability has gradually increased with the adoption of the radical abdominal operation; an exploratory operation is occasionally necessary. In advanced cases a preliminary curettage and cauterization is advisable. They describe the details of several cases and the technic.

4. In a paper describing tests for hepatic function, the writers find sugars to be theoretically unsatisfactory as tests for liver insufficiency and that the value of these tests from a practical point of view has been neither proved nor disproved.

5. The same writers as above mentioned describe in detail their experiments and investigations and results in animals on lactose tolerance as influenced by the liver necrosis of chloroform poisoning. [J. B. H.]

1. Griffiths describes in a plain and interesting way what are the functions of the large intestine, the rôle it plays in handling food, getting rid of waste matter and in metabolism in general. He reviews a subject that should be already fairly well known.

3. Morley cites three theories as explaining the growth of bone in muscles and fascia following trauma. These theories, which he discusses and explains are that this is due to: (1) tumor formation, (2) inflammatory changes, and (3) mechanical causes. He describes in great detail a case where this occurred, and discusses differential diagnosis, prognosis and treatment. He believes the process

to be similar to that of collus formation. In case of difficulty in diagnosis from sarcoma an exploratory incision is advisable. Single excision is usually followed by recurrence; conservative treatment is of little use; excision combined with grafting of deep fascia onto the denuded bone surface is the most likely to produce a cure. 6. ORR, J. *Note on Modern Prescription Writing.*

1. In this clinical lecture, illustrated with several plates, Falconer discusses in an interesting way on various abnormalities of pituitary secretion and their results in man.

2. This is an interesting discussion of a few cases of scarlet fever in the aged. The article is of value in that it calls attention to the fact that this condition is not so rare as is commonly supposed.

3. The Rumpel-Leede test for scarlet fever is elicited as follows: A bandage is tied tightly round the arm immediately above the elbow, with enough pressure so that the pulse is just perceptible at the wrist. It is kept in place ten to fifteen minutes, at the end of which time the arm should be markedly cyanosed. On removing the bandage the skin at the fold of the elbow distal to where the bandage was applied is examined for the reaction. This consists in the appearance of a widely varying number of minute petechial hemorrhages, fairly deeply seated which do not disappear on pressure, and are in fact made much more evident by stretching the skin. In the ordinary case no reaction is seen on the extensor surface of the arm. The usual explanation is that scarlatinal exanthema causes a certain "capillary vulnerability." Richardson found this reaction invariably present in a series of 210 cases of scarlet fever. No reaction was obtained before the rash had spread to the arms. In various normal persons and in those with other diseases, such as pneumonia, influenza, whooping-cough and chicken-pox the test was negative. In measles, rubella, and drug exanthems, the test was more often positive. In certain doubtful cases the writer believes this phenomenon to be an additional diagnostic sign.

5. Cyriax, evidently an enthusiastic believer in the beneficial effects of massage on certain circulatory diseases and others, describes in great detail, with the help of many excellent illustrations, his methods of treating various cardiac conditions. [J. B. H.]

2. Singer and Holzknecht state that the diagnosis of chronic appendicitis is often difficult on account of its indefinite signs and symptoms. The x-ray alone has proven of no value as a means for discovering this condition.

Singer and Holzknecht have studied in the following way, 25 cases which had suggestive symptoms of chronic appendicitis and were confirmed by operation or autopsy. The patients were given a bismuth-meal six hours and aften, in addition, thirty hours before exposure, in order to fill the large intestine with bismuth. They were then x-rayed and palpated at the same time, with a lead line drawn over the tender areas. By this method the position of the cecum, and large intestine with adjacent coils of small intestine, was mapped out in relation to the painful area, and the motility or fixation of these organs was determined. Thus Singer and Holzknecht believed that in chronic appendicitis they were able to make a more accurate diagnosis than by physical examination alone, and were able to differentiate appendicitis from disease of the pelvic organs, ureter, or from a ptosis which might account for the symptoms encountered.

8. Neumayer reviews the literature on the dosage of neosalvarsan. There has been a tendency among various authors to decrease the amount injected. From five years' experience with salvarsan, however, Neumayer believes that the best results in the treatment of syphilis are obtained by large doses of therapeutic agents. Therefore Neumayer gives men neosalvarsan in amounts corresponding to .8-1.00 gms. of salvarsan, and women a dose corresponding to .6-1.00 gms. of salvarsan. He has seen a few cases where transitory albuminuria developed, but otherwise has noted no ill effects. He concludes with Ehrlich that the number of relapses in syphilis are in inverse proportion to the intensity of the treatment and are reduced to a minimum the more energetically the early stages of the disease are treated. [R. F.]

BERLINER KLINISCHE WOCHENSCHRIFT.

9. LOEWY, E. *The Surgery of the Central Nervous System.*
10. RUNGE, E. *The Use of the Gonococcus Vaccine in the Gonorrhea in Women.*

2. The author reports two cases of recurrent cancer of the breast treated by local injections into the tumor, of benzol. He found that where the drug came into contact with the tumor cells, the latter were destroyed and the tissues in the immediate vicinity became necrotic. This was clearly a local action and the tumor cells outside the radius of activity of the benzol continued to grow just the same. His results do not argue strongly in favor of this treatment.

6. The author emphasizes especially the predisposing influence toward shock of fright, anxiety and nervous hyperirritability in the patient, and says that these should be avoided as much as possible during the induction of general anesthesia, and during the course of an operation under local or spinal anesthesia. He says that the chief seat of trouble in shock is in the medulla, and that noxious psychic stimuli coming to the medulla from the brain may at times have quite as much evil effect as afferent impulses coming to it from the injured periphery. To this end he advises the constant use of nitrous oxide in the induction of general anesthesia—that it may be as speedy and as comfortable for the patient as possible. [R. H. M.]

3. This is the continuation of the article reviewed in the September number of this journal. The authors take up here a study, first of the serum of those afflicted with the disease and others not. They find that in the serum of patients cured of this disease and in some of the people who remain immune in the midst of a severe epidemic who have been exposed, there are properties capable of destroying the poison in vitro. From a study of cases at different stages of the disease they find that the antibodies develop early in the disease. In fact they think that during the incubation period, before there is any evidence of the disease, the body is reacting to the poison and forming antibodies. The abortive cases show these same protective properties. [C. F., JR.]

10. *SMITH. *Some Bacteriological and Environmental Factors in the Pneumonias of Lower Animals, with Especial Reference to the Guinea-pig.*
11. *MEYER AND BOERNER. *Studies in the Etiology of Epizootis Abortion in Mares.*

1. Meyer shows that American paratuberculous enteritis is similar to the European form, one of the earliest cases of which was reported by Frothingham. The organism is a member of the "acid-fast" group, and is more closely allied to the Avian Tubercle Bacillus than any other. Inoculation experiments were successful in the three cases attempted. Radioscopic stool examination was positive in only 40% of the advanced cases. The author advises an investigation of "paratuberculin" and of serological reactions.

7. Haythorn has conducted a careful study of the pathological histology, in man and lower animals, of anthracosis. The investigation was carried out under ideal physical conditions, *i.e.* in Pittsburgh. He finds that the quantity of carbon taken up by the lining cells of the upper air passages and of the bronchi and alveoli is insignificant. Phagocytosis of pigment takes place by the endothelial cell, which is in all likelihood the large mononuclear basophile of the blood. These cells pass into the pulmonary lymphatics, where they often lodge and become surrounded by connective tissue. This lymphatic obstruction has a great pathological significance since it tends to limit the spread of tubercular processes and in that way promotes healing. But a detrimental effect is seen in the case of acute inflammatory conditions, *i.e.* pneumonias, since this lymphatic obstruction prevents rapid resolution and absorption. The presence of pigment granules in the "epitheloid" cells (endothelial) of the tubercle does not interfere with the cells' action in forming the lesion.

9. Orton finds the B. Aerogenes Capsulatus with greater frequence in the stools of residents of the hospital who have not been attacked by diarrhea or dysentery, than he does among the sick during or following the acute stages of this disease. The percentage of positive findings among students, living without the hospital, is somewhat smaller, but still large enough to throw considerable doubt upon the significance of this organism as a causal factor of dysentery.

10. Pneumonia in guinea-pigs is produced by the B. Bronchisepticus and by the Pneumococcus, the latter often secondary to the former. The motile bacillus lives from winter to winter in old pneumonic foci or in the air tubes. It is not found in the latter site in all guinea-pigs. The latter is a fact of importance in connection with the breeding of that animal.

11. In an outbreak of epizootic abortion in mares in Pennsylvania, Meyer and Boerner have established as an etiological factor a member of the paratyphoid enteritidis group, which they have called the B. abortus equi. Morphologically and biologically, it is more closely related to the group B. Paratyphosis B. than to any other. It is agglutinated by the specific serum to high degree and also by that of B. Paratyphosus B. and B. Enteritidis (Gaertner), though only in low dilution. The same organism was recovered from the fetal envelope in one case and twice from vaginal secretions in five infected animals. Artificial infection was produced by subcutaneous, intravenous, intravaginal and alimentary routes in a pregnant cow, goat, sow, and small animals such as

guinea-pigs and rabbits. The surest methods of diagnosis lie in agglutination and complement fixation reactions. [L. H. S.]

Obituary.

GEORGE HENRY TORNEY, M.D.

DR. GEORGE HENRY TORNEY, surgeon-general of the United States Army, who died of bronchopneumonia on Dec. 27, 1913, at Washington, D. C., was born in Baltimore, on June 1, 1850. After obtaining his preparatory education in Carroll College, New Windsor, Md., he studied medicine at the University of Virginia, from which he received the degree of M.D. in 1870. On Nov. 1, 1871, he was appointed assistant surgeon in the United States Navy, becoming a passed assistant surgeon on Nov. 1, 1874. On June 30, 1875, he resigned from the navy, and was immediately appointed assistant surgeon in the United States Army. He was promoted to the rank of captain on July 1, 1880; became surgeon major on June 6, 1894; and in the latter position saw active service in Cuba during the Spanish War, and subsequently in the Philippines. He was made lieutenant colonel and deputy surgeon-general on Aug. 8, 1903; and on April 23, 1908, received the rank of colonel of the Army Medical Corps. On Jan. 14, 1909, he was appointed surgeon-general of the United States Army, a post which he filled ably until his death. He was a member of the American Medical Association, the Association of Military Surgeons of the United States, and the American Red Cross.

Miscellany.

REPORT OF COMMITTEE ON THE STANDARDIZATION OF HOSPITALS.*

WE have believed it to be the wish of this congress that we should examine the ways and means by which this body might best do its share in the general movement which the public is beginning to demand toward increasing the efficiency of hospitals.

We shall presently offer to you three definite suggestions for action by which you may materially aid this important movement, but first we should like to call your attention to the method by which we have approached this subject.

By what standards can we compare hospitals? It is obvious that there are many. There may be a standard of architecture, of cleanliness, of kindness to the patients, of nursing, of medical education, etc. To some persons the per capita cost, the number of patients annually treated, the success in private practice of their medical and surgical staffs, the quality of the scientific papers produced, or the up-to-dateness of the laboratories may seem the important elements. Some hospitals seem satisfied with the famous contributions to medical science which some member of their staff made a hundred years ago!

We believe that you will agree with us that even cleanliness, marble operating rooms, famous physicians and surgeons, up-to-date laboratories and time-honored reputation do not necessarily mean that the individual patient will today be freed from the symptoms for which he seeks relief.

Even the standard of kindness cannot replace the actual facts of the relief or prevention of symptoms or of the prolongation of life. For does a scientific paper written about the autopsy give the patient the satisfaction that a successful operation might have done!

The more time we have spent on this subject, the more obvious it has seemed to us that the only firm ground on which we can compare hospitals is by the actual results to the individual patient. Even a statistical comparison of the results of the treatment of the disease is less satisfactory. A patient operated on at the same sitting for fibroids of the uterus, gallstones and epithelioma of the nose cannot properly be classified under one of these headings for comparison with other individuals, nor does this combination of diseases form a group frequent enough to tabulate.

A comparison of the morbidity reports of many of the best institutions in this country has convinced us of the futility of the great labor and expense which has been expended on them. Owing to diversity of methods of classification they are not comparable except in the most gross way. Some are arranged by disease alphabetically, some by regions, and others by elaborate systems modelled after the International List of the Causes of Deaths.

Our impression of the futility of such praiseworthy efforts without coöperation and coördination, we have found to be shared by the members of the staffs of even those institutions making the greatest efforts in this direction. We believe that those who compile these statistics would welcome a more simple and direct form. We also believe that it is almost useless for one hospital to undertake statistics of this kind unless other similar institutions adopt like methods.

Since these tables are compiled only from the condition of the patient at the time of discharge from the hospital, they are at best a mere rough statement of immediate mortality and do not represent the real result to the patient of the treatment received. Nevertheless, we are convinced that no standardization of hospitals can be fair which is not based on what

* Presented at the meeting of the Clinical Congress of Surgeons, Chicago, Nov. 11, 1913.

the hospital is actually doing for its individual patient, and that some form of hospital report must be devised which will show that each hospital is, at least, making an effort to ascertain whether the results of its treatment are satisfactory or not. From this point of view a successful operation done in a barn is equivalent to a similar one done in an expensive modern operating room. Likewise, one which was unsuccessful because a famous surgeon or teacher was careless or pressed for time is worse than one which failed because the operator was not a member of the American College of Surgeons!

Further personal investigation of a number of the best institutions in the country developed the astounding fact that no effort is made to trace the patient beyond the gate of the hospital except such investigation as is individually made by members of the staff for their own interest. A patient might be operated upon, leave the hospital with the wound healed, and yet no effort be made to record the result of the operation. In other words, we have the paradox that neither the hospital trustees, the physician, or the surgeon or administrator consider it their business to make sure that the result to the patient is good.

A factory which sells its product takes pains to assure itself that the product is a good one, but a hospital which gives away its product seems to regard the quality of that product as not worthy of investigation.

In a way, trustees of hospitals who do not investigate the results to their patients do not audit their accounts.

We believe it is the duty of every hospital to establish a follow-up system, so that as far as possible the result of every case will be available at all times for investigation by members of the staff, the trustees or administration, or by other authorized investigators or statisticians. We believe that the publication of such material in abstract by case numbers is practical and does not entail a disproportionate expense.

The committee have distributed a leaflet suggesting a form of report based on the idea of a brief abstract of the individual case. Such a report would, at least, be uniform in character and could be expanded indefinitely, according to the means of the hospital. It would, at least, show the essential fact of whether the hospital was making an effort to trace its cases. It would also put its material at the service of medical science in a form much more practical to a statistician than even the best prepared morbidity reports at present published.

If hospitals kept such abstracts in available form, even if not published, we believe that the practical standards of their work would be greatly improved and that a definite basis of the comparison of the efficiency of such institutions would be fixed.

A method such as suggested is at present in use at the Massachusetts General Hospital of Boston, and other similar plans are being tried by a few other institutions.

It would be obviously inappropriate for this Clinical Congress of Surgeons to attempt any specific suggestion as to forms of hospital reports. Bodies such as the American Medical Association and American Hospital Association are more fitted to do this since they represent general medical science and not a special branch.

Your committee has been in touch with the various committees of these associations and has found them already actively working. The committee of the American Medical Association on medical education, whose chairman is Dr. Bevan, has approached the Carnegie Foundation with a petition that it should investigate the efficiency of American hospitals after a similar manner to that in which they recently investigated medical education. Since such an investigation would entail great expense and require much time and effort it is unlikely that an unpaid board from the medical profession would be able to conduct it thoroughly. It is also probable that such a question of efficiency would best be studied by modern efficiency engineers—not by medical men with preconceived ideas. For these reasons your committee would favor any action you may see fit to take in adding the petition of this body to that of the American Medical Association and American Hospital Association to broaden the scope of the investigation beyond that of medical education.

As it is highly probable that the Carnegie Foundation will undertake this matter, at least so far as it concerns medical education, we may now consider what this congress can do to aid them.

Representing, as you do, almost all the hospitals of the country, there is much which you may accomplish by a united or rather a uniform effort. It is safe to assume that those employed by the Carnegie Foundation will thoroughly investigate such matters as business efficiency, laboratory equipment and the relations of medical education, etc.

It is in matters connected directly with the results of surgical treatment in which they will need your help. When you return to your hospitals you can do much to aid the coming Carnegie representative by systematizing the methods which you already use to trace the results of your operations. If you have no such system, you would do well to get your hospital to establish one now, for the demand for it is sure to come. In our leaflet we have offered you some suggestions.

When a follow-up system is once established it will do much toward weeding out the superannuated, the lazy and ill-trained surgeons of your community, even though they hold high places. The delayed misfortunes of the brilliant operators who do not do the right thing will appear from the invisible, and the true surgeon

who uses his knife to relieve and prevent suffering will come to his own.

Remember that when the question of efficient treatment comes up, that it will be the results of the surgeon which are the easiest to put in the limelight.

Your committee, therefore, have to offer the following three suggestions:

1. That this congress give the stamp of its approval to an investigation of hospitals by the Carnegie Foundation and empower its representatives to urge the Foundation not to limit their inquiries purely to the bearings on medical education, but to classify hospitals according to their actual efficiency.

2. That each of us do what we can to induce the trustees of our own hospitals to organize a follow-up system for all patients treated.

3. That each of us do what we can to induce the fellow members of our staffs to appoint efficiency committees who may look into present conditions in our hospitals, in order that we may, as far as possible, do our own housecleaning.

Such efficiency committees should be composed of a member of the trustees, a member of the staff and a superintendent.

If tracing the results to the patients is equivalent to auditing the accounts, the trustees should take a hand in it.

In closing this report your committee wishes to again state their conviction that the essential factor which will most contribute to raising the standard of American hospitals is the establishment in each hospital of a follow-up system of tracing the outcome of treatment given to each individual patient.

We have spoken of a united or uniform effort on the part of individual members of this congress, and we urge you in the strongest way to obtain at your own hospitals the establishment of efficiency committees on which the trustees or managers, as well as the staffs, are represented.

Let us make this effort uniform. Let us not have the efficiency committee composed in some hospitals entirely of members of the staff, but let us aim to have all three of the important branches of hospital management represented so that each may bear in part the burden of the responsibility to the community of the efficient treatment to the individual.

Let it not be said, as it may justly be at present, that neither the superintendent nor the manager nor the staff feel it their duty to ascertain whether the product of their hospital is sound or damaged.

E. A. CODMAN, M.D., Boston, *Chairman*,
W. W. CHIPMAN, M.D., Montreal,
J. G. CLARK, M.D., Philadelphia,
A. B. KANAVAL, M.D., Chicago,
M. J. MAYO, M.D., Rochester, Minn.

MASSACHUSETTS MEDICAL SOCIETY.

SPECIAL MEETING OF COUNCIL.

A special meeting of the council of the Massachusetts Medical Society was held December 30, 1913, at twelve o'clock, noon, in Sprague Hall, Boston Medical Library, with the president, Dr. W. P. Bowers, in the chair. There were sixty-two members of the council present.

The records of the last meeting were read and accepted.

Dr. Hugh Cabot spoke on the midwife question. He thought the society through its council should give definite instructions to its committee hearings at the State House, this committee has been made to appear without authority and the policies which it favors are regarded as personal expressions of opinion rather than those advocated by the Massachusetts Medical Society. Dr. Cabot presented the following letter to the president, which was signed by the Obstetrical Society of Boston and by forty-four physicians of Boston, Haverhill and Springfield:

Last year in the legislature, by House Bill No. 678, an attempt was made to legalize the midwife and admit her on equal terms with the physician to the practice of Obstetrics. Certain members of the Massachusetts Medical Society favored this bill. In all probability there will be another attempt this year to legislate in the midwives' favor. By a decision of the Supreme Court handed down by Justice Rugg, Commonwealth v. Porn, the midwife was excluded from practicing obstetrics. Yet in Chapter 29 of the Revised Laws of the Commonwealth, the word midwife repeatedly occurs (Section III, "a midwife shall make and keep a record, etc.", "the fee of the physician or midwife shall be twenty-five cents;" later, "the physician or midwife who neglects"), thus seeming to give her a legal status. There are persistent reports about Boston that members of the Massachusetts Medical Society are signing birth returns of infants delivered by midwives, the physician not being in attendance. We, the undersigned, members of the Massachusetts Medical Society, feel that the practice of obstetrics is a vital and essential branch of the practice of medicine and that no training other than that leading to the degree of M. D. is to be considered adequate or sufficient for engaging in this practice. We recognize that this consideration may, however, demand an ideal situation. Therefore, until public sentiment can be roused sufficiently to raise the standard of obstetrics so that the midwife is admitted to be an unnecessary evil, we advise that no legislation should be sanctioned by the Massachusetts Medical Society other than bringing the statute books up to date by omitting the word midwife wherever it occurs in those sections pertaining to the reporting of births.

As a step in advancing the status of the practice of obstetrics, we ask you to bring before the council of the society the proposal that the practice, said to be carried on by certain doctors, of returning birth certificates on cases over which they have had no supervision, and failing to state that they were not in attendance, is contrary to the ethics of this society; that any member so doing is guilty of a misstatement of fact and should be debarred from the privileges of this society.

(Letter addressed to the president, dated Oct. 6, 1913)

In order to bring the matter into definite form, Dr. Cabot presented the following preambles and resolutions:

Whereas, by Chapter 76, Sections 8 and 9, of the Revised Laws of the Commonwealth of Massachusetts, the midwife was excluded from the practice of her profession within the confines of this state, and by a decision of the Supreme Court handed down by Justice Rugg in the case of the Commonwealth v. Porn the law was held to directly cover the activities of the midwife and thus made effective:

And whereas, Chapter 29 of the Revised Laws of the Commonwealth of Massachusetts repeatedly uses the word *midwife* (Section 3, "Physician and midwife shall make and keep a record," etc., and later, "the fee of the physician or midwife shall be twenty-five cents," etc., and later, "the physician or midwife who neglects," etc.), thus seeming to give her legal status;

And whereas, by House Bill 678 presented to the Great and General Court of the Commonwealth of Massachusetts, January 9, 1913, a definite, although unsuccessful, attempt was made to legalize the midwife and admit her on equal terms with the physician to the practice of obstetrics, this bill being favored by certain members of the Massachusetts Medical Society;

And whereas, persistent reports are being received that members of the Massachusetts Medical Society are signing birth returns for infants delivered by midwives without a physician in attendance;

Be it resolved, that we, the council of the Massachusetts Medical Society, put ourselves on record as of the firm opinion that the practice of obstetrics is a vital and esssential branch of the practice of medicine, and requires the care and supervision of a graduate in medicine, and that there is no place for the untrained practitioner in this field of medicine within the Commonwealth of Massachusetts: that no training other than that leading to the degree of M. D. is to be considerd adequate or sufficient for engaging in this practice; that untrained persons practicing obstetrics are in open defiance of the law and should be prosecuted when apprehended; that as soon as public sentiment within and without this society can be sufficiently aroused, a bill shall be presented to the Great and General Court of the Commonwealth of Massachusetts which shall provide for the omission of the word *midwife* from the statute books, thus bringing the law up to date; that members of this society are hereby enjoined from handing in birth returns on cases over which they have had no supervision when delivered by a midwife; and that it is the opinion of this body that a physician signing a birth return assumes the responsibility for that case.

These were discussed by Drs. H. P. Walcott, F. C. Shattuck, H. D. Arnold, F. E. Bateman, C. H. Cook, the president and Dr. C. F. Withington. Dr. Withington pointed out four alternatives that are open at this time: 1. To leave the present law; 2. To leave the present law with the elimination of expressions which tolerate or legalize midwives; 3. To legislate positively prohibiting midwives to practice; and 4. A licensure of midwives after examination.

The question was further discussed by Dr. Buckingham and others. The preambles and resolutions being put to vote, were adopted unanimously.

It was moved and

Voted, That the committee on ethics and discipline be directed to look into the matter of the signing of birth certificates by fellows who have not been actually in attendance, and to take such action as it deems advisable.

Dr. M. W. Richardson, for the committee on public health, presented the question of ophthalmia neonatorum, and made the following motion:

Moved, That the council approves amending Section 49 of Chapter 75, of the Revised Laws relative to the better control of ophthalmia neonatorum as follows:

"Section 49 of Chapter 75 of the Revised Laws is hereby amended by adding after the word "necessary" in the eighteenth line, the following words: "including as far as may be possible consultation with an oculist and the employment of a trained nurse."

This was discussed (by invitation) by Dr. F. E. Cheney. He said that in recent years he had treated many cases of ophthalmia neonatorum at the Massachusetts Charitable Eye and Ear Infirmary; that last year in 20% of the cases that were admitted blind, the blindness was due to ophthalmia neonatorum. He read extracts from data as to seven members of the Massachusetts Medical Society who had been derelict either in reporting or in treating cases of ophthalmia neonatorum, most of these being in the neighborhood of Boston, and none in the remote country districts. The inexperienced practitioner rarely notices the involvement of the cornea in these cases, and thinks that because the discharge has become less, the cornea is not affected. Dr. Cheney thought that the Massachusetts Medical Society should go on record as opposed to the treatment of cases of ophthalmia neonatorum by the general practitioner, and he favored Dr. Richardson's motion. After some further discussion, the motion was put by the president and passed unanimously.

Dr. M. W. Richardson, for the committee on public health, read the five sections of an act to enable the State Board of Health to better protect the public health through adequate supervision of the conditions under which milk is produced, transported, kept for sale and sold, and he moved that it be approved by the council; and on being put to vote, it was approved unanimously.

The president nominated the following as a committee to audit the treasurer's accounts, and they were elected:

D. N. Blakeley, Brookline
J. L. Huntington, Boston.

Dr. Homans, for the committee of arrangements, asked for advice from the council as to the annual dinner. He pointed out that the expense had increased of late, and queried whether it was worth while to spend so much on the dinner when the other activities of the society needed part of the funds. His committee planned to charge a nominal amount, say one dollar apiece, to cut down the expense of the dinner, but not to change the character of the dinner; and he made a motion that the committee of arrangements be instructed if it sees fit to impose a charge of one dollar on all fellows who attend the annual dinner.

Dr. Broughton pointed out that the last dinner was not more expensive per diner than

usual, but that more fellows attended; and that each one over one thousand (the number contracted for) costs fifty cents extra. Dr. Hough said that he didn't see why the two-thirds of the society who did not attend should pay for the third who ate the dinner, and that he thought there were very many fellows who did not require an elaborate dinner and would rather have the funds of the society expended for more worthy ends.

Motions were made to substitute two dollars and three dollars in place of the one dollar in the original motion. On being put to a vote, these were lost.

On motion by Dr. Arnold, the words "if it sees fit" were struck out of the motion, and the amendment being accepted by Dr. Homans, the motion was passed as amended.

Dr. Goss, for the committee on membership and finance, reported as follows:

The committee on membership and finance reports that at a meeting of the council held October 1, 1913, the following votes were passed:

I. That its secretary be instructed to send to each member of the society a copy of that part of the report of the Judicial Council of the American Medical Association which refers to secret fee splitting and "contract practice."

II. That the president be empowered to direct the legal counsel of the society to bring before the Superior Court, and if need be before the Supreme Court, a test case under Part III. Sections 11 and 16 of the Workman's Compensation Act (Chap. 751, Acts of 1911, as amended by Chaps. 172 and 571, Acts of 1912) in order to clear up in part the vexed matter of the ultimate payment of physicians' fees in disputed cases.

By direction of the president, these votes were referred to the committee on membership and finance. A meeting of the committee was held October 13, 1913, and after full discussion, it was voted to recommend to the council that $64.00 be appropriated from the treasury of the Massachusetts Medical Society for the printing and distribution to its members of that part of the report of the Judicial Council of the American Medical Association relating to secret fee splitting and contract practice.

Also, that $100.00 be appropriated to enable the legal counsel of the society to bring before the courts a test case to clear up in the Workman's Compensation Act the matter of the ultimate payment of physicians' fees in disputed cases.

Voted, To accept the report and adopt its recommendations.

The report of a committee appointed to consider the petition of one former fellow for reinstatement was accepted and six committees were appointed to consider the petitions for reinstatement of six former fellows.

The treasurer spoke of the case of the estate devised under the will of Isaac P. Smith, a fellow of the Massachusetts Medical Society, who died in 1862, late of Gloucester, and said that the Massachusetts Medical Society is a residuary legatee but that there are so many young heirs-at-law the possibility of the society's receiving anything from the will is rather remote. He queried whether the president had authority to sign documents relating to the estate submitted by the trustee, and whether the society should bear any of the legal expenses connected therewith.

On motion by Dr. H. P. Walcott, it was

Voted, That the president be authorized to do as he sees fit in the case of the Isaac P. Smith will, without expense to the society.

Voted, That the two bills submitted by the committee on public health be introduced to the legislature by some member of the council, and that the committee on state and national legislation be instructed to support the measures.

The president announced the death on December 20th, of Dr. A. E. Mossman, of Westminster, councillor and supervisor.

Adjourned at 1.45 P. M.

WALTER L. BURRAGE,
Secretary.

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE 3 WEEKS ENDING DEC. 27, 1913.

December 10, Surgeon R. R. Richardson, detached: *Virginia* to *New Jersey*.

Surgeon G. L. Angeny, detached: *New Jersey* to *Virginia*.

P. A. Surgeon G. B. Crow, detached: Naval Medical School, Washington, D. C., to Naval Hospital, Brooklyn, N. Y.

P. A. Surgeon C. E. Strite, detached: *Virginia* to *Michigan*.

Assistant Surgeon J. J. O'Malley, detached: *Albany* to home, wait orders.

December 12, P. A. Surgeon P. R. Stalnaker, detached: *Prairie* to New York Hospital, for treatment.

P. A. Surgeon E. L. Woods, ordered to Naval Proving Grounds, Indian Head, Maryland, temporary duty.

December 13, P. A. Surgeon J. B. Pollard, ordered to *Prairie*.

P. A. Surgeon H. F. Strine, detached: Norfolk Hospital to *Solace*.

Surgeon A. M. Fauntleroy, detached: *Solace* to waiting orders.

P. A. Surgeon L. W. McGuire, to Receiving Ship at Norfolk, Va.

December 17, Surgeon H. A. Dunn, detached: *Solace* to *Kearsarge*.

Surgeon W. M. Garton, detached: *Kearsarge* to *Solace*.

December 23, Surgeon D. N. Carpenter, detached: *Tennessee* to First Regiment, Advance Base Brigade.

P. A. Surgeon L. W. McGuire, detached: Receiving Ship, Norfolk, Va., to First Regiment, Advance Base Brigade.

P. A. Surgeon F. X. Koltes, detached: *North Dakota*, to First Regiment, Advance Base Brigade.

P. A. Surgeon C. F. Charlton, detached: *Panther*, to First Regiment, Advance Base Brigade.

Assistant Surgeon R. F. Sheehan, detached: Atlantic Reserve Fleet, to First Regiment, Advance Base Brigade.

SOCIETY NOTICE.

THE BOSTON SOCIETY OF MEDICAL SCIENCES.—The next meeting will be held on Tuesday evening, January 13, 1914, in the out-patient amphitheater of the Massachusetts General Hospital, at 8.15 o'clock.

The meeting will be conducted by the staff of the Massachusetts General Hospital, Dr. Roger I. Lee, secretary.

Papers will be presented as follows:

Dr. C. A. Porter, "Graves' Disease." (15 minutes.)

Dr. J. H. Pratt, "Uric Acid Content of the Blood in Gout by the Method of Folin and Dennis." (15 minutes.)

Dr. A. E. Steele, "Cornyebacterium Hodgkini in Lymphatic Leukemia and Hodgkin's Disease." (5 minutes.)

Dr. W. A. Hinton, "Lange's Colloidal Gold Test in the Cerebro-spinal Fluid." (15 minutes.)

Dr. F. B. Talbot, "Respiratory Metabolism of Infants." (15 minutes.)

THOMAS ORDWAY, *Secretary and Treasurer*,
Harvard Medical School.

MASSACHUSETTS GENERAL HOSPITAL.

A surgical meeting open to the Medical Profession will be held at 8.15 p.m., Friday, January 9, 1914, in the lower amphitheatre of the Out-patient Department. Entrance on either Blossom or Fruit Streets.

DR. FARRAR COBB will present: "Cancer of the Uterus with Comparative Analysis of the Hospital Cases and End Results, with Special Consideration of the Radical (Wertheim) Operation for Cancer of the Cervix."

DR. HAROLD GIDDINGS will present: "A Preliminary Report on the Study of Blood Pressure in Hysterectomies and other Radical Operations."

APPOINTMENTS.

BOSTON BOARD OF HEALTH.—*Dr. James J. Scannell*, of this city has been appointed director of the bacteriologic laboratory of the Boston Board of Health.

BOSTON DISPENSARY.—*Dr. Edward O. Otis* has been appointed consulting physician and *Dr. Robert W. Lovett* consulting orthopedic surgeon. Dr. Otis is just retiring after a service of 27 years in the tuberculosis department, which hereafter will be united with the department of internal medicine. *Dr. A. Warren Stearns* has been appointed physician in charge of the department of mental diseases. *Dr. P. S. McAdams* has been promoted to be surgeon in the ophthalmic department, *Dr. Robert L. De Normandie* in the gynecologic department, and *Dr. Hilbert F. Day* to be assistant surgeon in the general surgical department.

RESIGNATION.

It is announced that DR. WILLIAM ALLEN BROOKS, of Boston, has resigned his position as surgeon-in-chief of St. Elizabeth's Hospital in this city.

RECENT DEATHS.

DR. EMMA E. MUSSEN, who died at Philadelphia on Dec. 28, was born in 1863. She was a member of the American Medical Association, and professor of otology at the Woman's Medical College, Philadelphia.

DR. FRANK H. O'CONNOR, who died of cardiac disease on Dec. 26 at Brattleboro, Vt., received the degree of M.D. in 1898 from Long Island Medical College. He was on the surgical staff of the Brattleboro Hospital.

DR. HENRY STIER POLL, of Virginia Hot Springs, who died of cardiac disease recently in Lewisburg, W. Va., was born at Baltimore, Md., in 1845. He had practised his profession at Hot Springs since 1867. He is survived by his widow and nine children, two of his sons being also physicians.

DR. CHARLES PHELPS, of New York, died on December 30. Dr. Phelps was born on December 12, 1834, in Milford, Mass., and was a lineal descendent of William Phelps, who came to Massachusetts in 1630. He was graduated from Brown University in 1855 and from the College of Physicians and Surgeons, New York, in 1858. He was a contract surgeon during the Civil War, and had practised in New York from its close until 1909, when he retired. For forty years he was surgeon to Bellevue and St. Vincent's Hospitals, and at different times he served as president of the New York State Medical Society, the medical board of Bellevue Hospital, and the board of police surgeons. He was the author of a work on injuries of the brain, as well as of numerous surgical papers. He is survived by his widow and by one son.

DR. ALFRED E. M. PURDY, a widely known physician of New York, died on December 25. He was the son of Dr. Alfred S. Purdy, and was graduated from the College of Physicians and Surgeons in 1861. Dr. Purdy was for many years editor of the Medical Register of New York, New Jersey and Connecticut, now superseded by the Medical Directory, published by the State Medical Society, and recording secretary of the Medical Society of the County of New York. He was also the organizer of the Methodist Episcopal (Seney) Hospital in Brooklyn, to which he was consulting physician at the time of his death.

DR. HOWARD BECK REED, of Seabright, N. J., the son of Dr. James J. Reed of that place, died at the Neurological Institute, New York, on December 27. He was graduated from the medical department of Columbia University in 1910.

DR. SILAS WEIR MITCHELL, of Philadelphia, died of broncho-pneumonia in that city on Jan. 4, at the age of 85 years.

DR. J. FRANCIS DE SILVA, who died last week at Atlantic City, N. J., was born in 1875, and graduated in 1900 from the University of Pennsylvania.

Original Articles.

A STUDY OF CANCER.

BY SEELYE W. LITTLE, M.D., ROCHESTER, N. Y.

LET it be plainly stated at the outset that the writer does not claim to present a "cure for cancer." He does maintain that the theory here offered is at variance with no known facts, that it explains many hitherto puzzling facts, and that the practical clinical results obtained in every case of scientifically proven cancer and in every case of clinically certain cancer thus far put to the test not only confirm the general truth of the theory, but convincingly indicate that ultimately "cure" is possible. This goal can be reached, however, only by careful scientific treatment of many cases with recorded findings. Warning must be given that inoperable cases alone should be considered until we have more clinical data. Otherwise we are playing with fire.

The writer has much misgiving as to the wisdom of publishing so unfinished a report. He first submitted the report to about thirty of the best medical men in the vicinity and it is through their advice that he now publicly asks that his ideas be put to a general trial that we may the sooner know their true worth.

Acknowledgment should be made to numerous investigators all over the world, for without their long and careful research this report would be not only worthless but impossible. The facts stated can be easily verified by anyone familiar with the literature. It is unnecessary to give the list of authorities as such a list would cover many pages. To any physician interested, however, the author will gladly furnish the source of his information on any point.

Cancer appears primarily only in highly specialized cells. It is presumed that, like other highly specialized things, these cells are comparatively easily gotten out of order; that, doing special work, they need outside help to enable them to do the things an unspecialized cell does for itself, *i.e.* have their food properly prepared, their waste matter properly cared for, etc.,—in short, their nutrition. For this purpose certain cells from the same blastodermic layer are set aside to specialize in this nutrition business. This statement is made here without comment. The evidence in favor of its truth will appear later. These are the so-called ductless glands. As the special work in each case is increased there is a corresponding increase in work of the corresponding cells. For example, during growth the thymus is large and active. The reverse is also true normally; when the need for the special work slackens there is a corresponding slackening of work of the corresponding cells. The thymus (again as a single example) atrophies normally when its work is done, about the time of adolescence. So as age advances both the activity of the specialized cells and the activity of the nutrition governing specialized cells (the ductless glands) normally diminish *pari passu* to a normal physiological death.

Now suppose the balance is upset in any way. The specialized tissues may be overworked to such an extent that their specialized helpers cannot keep up with them; the helpers (the ductless glands) may be congenitally too large and active or too small and inactive; they may by accident or disease likewise over or under functionate; either the ductless glands or the specialized tissues they govern metabolically may from overwork, accident or disease begin their physiological death before their complementaries. We then, in every case of such unbalance, have a pathological process arising,—a disease in short. With some such processes we are fairly familiar: Addison's disease, Graves' disease, myxedema, for example. The conclusion is inevitable that there are other pathological conditions, the basis of which is deranged metabolism and which are caused by similar lack of balance in these highly specialized organs. We have already acquired from many patient workers an immense array of known facts concerning hyper and hypo function of the ductless glands and concerning absolute failure of such glands. Many of the proven facts seem absolutely contradictory, but that must be because we do not yet know the whole truth. One stumbling block is the assumed interrelation of these organs, one hypertrophying when another is quiescent, one apparently preventing the action of another or aiding such action. It is certain that removing one of these glands from an organism does not produce the exact opposite to an excess of the secretion of the same organ, the others being normal in each case. But there is another explanation than the assumption that one deters or aids another, as the case may be. An analogy will best show what is meant. Suppose a man with very poor teeth. Such a man is very apt to have indigestion, though the digestive organs are perfectly normal. He is then apt to be badly nourished, not part of him, but all of him, brain, bone, muscle, everything. But it would be absurd to attribute the irritability of the undernourished nerves, for instance, to an essential correlation between teeth and nerves in the sense that the thyroid and the suprarenals are supposed to be correlated. In the case of teeth and nerves we recognize easily the sequence to be purely mechanical because we can follow every step of the process. Is it not at least as good a hypothesis as any that the thyroid secretion is perfectly independent essentially of the suprarenal secretion and that the apparent intimate relation between them is really an indirect relation, precisely as teeth and nerves are indirectly related? That is, supposing the thyroid secretion fails.

Certain tissues of the body fail to get what they need. In turn they cannot deliver their quota to the organism and the whole organism necessarily suffers more or less, including other ductless glands. At all events, it is certain that failure or excess of secretion of one of these glands soon or late affects the others more or less with resulting symptoms. So no two cases of Addison's disease or of myxedema or of acromegaly or of Graves' disease will be exactly alike and in part may be widely different.

Another thing to consider is the probability of two or more of these organs being primarily at fault in some cases. When we think of the variations possible, the complexity of symptoms in certain cases is no less puzzling, but is at least more capable of explanation. Take, for example, only two glands and arrange the possible combinations which would produce a lack of balance in the whole organism. Such combinations would be in number, as follows, A and B representing the glands:—

1. A hyper
   B normal
2. A hyper
   B hyper
3. A hyper
   B hypo
4. A hypo
   B normal
5. A hypo
   B hyper
6. A hypo
   B hypo
7. A normal
   B hyper
8. A normal
   B hypo

Every one of these combinations would necessarily produce different symptoms. Nor is this all by any means. The degrees of hypo or hyper secretion in each combination may vary without limit. So our puzzling symptoms may remain puzzling but at least solution is seen to be a possibility.

The theory that these internal secretions have direct normal physiological relations with each other in the sense of aids or antagonists does not appeal to the writer. On the contrary, the theory that each secretion is independent of all the others, except in the sense that each is essential to the whole organism and therefore to the working of the others, does seem reasonable. The external secretions work that way. The gastric juice as such is self-sufficient. It neither has nor needs the aid or the inhibition of any other secretion to do its designed work. But if the pancreas is not working correctly, then certainly in time neither will the stomach, not because pancreatic juice is essential as such for the proper working of gastric juice, but because the stomach as well as any other muscle in the body must have its supply of properly prepared carbohydrate food which a normal pancreas can furnish. If the stomach cannot get this particular food it in turn cannot produce a proper gastric juice. It is an indirect relation, not a direct one. Why then assume otherwise in the case of the internal secretions?

Another consideration leads to the same conclusion. The thyroid and the suprarenals are considered in certain directions to be antagonists because they seem to produce opposite effects. But they are derivatives of different germ layers, the suprarenals from the ectoderm and the mesoderm and the thyroid from the endoderm. Also all the successful efforts at therapeutic use of the internal secretions have been either supplying the particular failing secretion or removing the organ doing the hypersecretion; never by administering a so-called antagonist in the case of oversecretion or an "aiding" secretion to help out the failure of an undersecreting organ. For myxedema we give thyroid and for Graves' disease we remove some of the hypersecreting thyroid. To be sure, we do not always succeed. In Addison's disease adrenalin by no means always cures, but for very good reasons unnecessary to discuss here. Suffice it to say that there are practical and mechanical difficulties in a theoretically perfect administration of adrenalin in Addison's disease.

On all accounts it seems more reasonable and certainly more hopeful to consider each internal secretion as essentially self-sufficient and as furnished for some definite work in the economy. Also it is reasonable and highly probable that this purpose is in connection with those tissues in the body derived from the same germ layer as the gland in question. In other words, the thyroid can have no direct function on any but tissues derived from the endoderm, the pituitary body on any but tissues derived from the ectoderm and so on. Table 1 gives all the tissues in the body derived from each of the germ layers. At once an apparently obvious objection arises to this idea. The absolute failure of the thyroid, for example in an infant, may result in a cretin. One of the characteristic symptoms of cretinism is failure of bones to develop properly, and in this case nearly all writers ascribe the bone failure to lack of thyroid and therefore ascribe proper development of bones to proper thyroid secretion. But bones are mesodermic structures and thyroid is endodermic and the theory seems knocked in the head. Nevertheless, another explanation is possible. Certainly bones do not develop properly in a young thyroidless animal, but this may just as well be an indirect result of hypothyroidism. If the thyroid's work is entirely with endodermic tissues it still has a very wide field, all the digestive tract for example. Now it may easily be, in fact must be, that if the digestive tract fails for lack of thyroid, so will all other tissues in the body, bones included. A similar explanation would suffice for all the

other known cases where an internal secretion derived from one blastodermic layer seems to affect tissues of a different blastodermic layer. In fact, as one might expect, all those internal secretions of which we have accurate knowledge actually do affect tissues of widely different origins, but it is just as easy to understand how that is possible indirectly as directly and far more rational.

With this idea as a basis many nutritional diseases at once assume a different aspect and a hopeful aspect instead of a hopeless. Just as an astronomer may be absolutely certain from the behavior of known planets that there must be another unknown planet of a certain size and position, so if we had only known all the facts about, say the thyroid, we could have predicted absolutely that there must be somewhere in the body, without actually having found it, a body like the parathyroid. Likewise we could write out an accurate description of myxedema without ever having heard of it or seen it. We do not, however, know all the facts about the thyroid or any of the other internal secretory organs. We do know a good deal about many puzzling diseases of a plainly metabolic nature, and even with our imperfect knowledge it is decidedly worth while to try to fit these facts together. Often there are too many facts missing to get a satisfactory result but occasionally, just as in a picture puzzle, one piece that has been before our eyes all the time fairly leaps into place and the whole thing is clear, so one long known fact may suddenly be set in its right relation, with the result that the disease and its logical cure are at once plain. An illuminating example of this is malaria. All the essential facts were known for years, but not until the mosquito, an apparently unrelated fact, was put with the other plainly relevant facts were the disease and its prevention at a stroke comprehended.

In studying various diseases of faulty metabolism it suddenly occurred to the writer that cancer is absolutely and essentially such a disease, and at once many things became clear. Let us first set down certain known facts concerning cancer.

1. It occurs originally only in highly specialized cells of epithelial type.

2. Overwhelmingly a disease of the downhill time of life when physiological death has begun its slow course.

3. Generally, perhaps always, a disease first attacking injured cells *i.e* trauma is a predisposing cause.

4. A disease increasing as the complexity of civilization increasingly puts extra strains on the organism.

5. A disease habitually progressing in its course at an ever accelerating pace to death of the organism.

6. A disease especially liable to recur even after most thorough removal of the original focus.

7. A disease generally more rapid the younger the patient; that is, the more vigorous the metabolism, the sooner is havoc wrought by any interference. Exactly as the wreck is more disastrous and speedy from interference with rapidly moving than with slowly moving machinery.

8. Most astonishing of all and perhaps least emphasized of all is the fact that this disease is almost unique in one thing—it is tissue reproduction at a time of life when normally every part of the body is physiologically dying and tissue reproduction failing. Why certain cells at this time should begin to reproduce themselves (atypically to be sure but still reproducing) has always been a puzzle. Not so puzzling, however, if we consider cancer a disease of faulty metabolism as will be discussed later. The growth of fat at about middle life seems to be the only normal growth at such time—and fat is not a high type of tissue.

If we now piece together all the known facts of cancer and all the known facts as to the internal secretory organs we shall evolve a theory of cancer satisfying all the known conditions, hopeful, and very much more convincing than any previous theory.

Let us start then with the idea that this unique reproduction of cells at a time of life when such reproduction has normally ceased, is due to a relative oversecretion of glands known normally at an early age to influence tissue growth. A serious objection at once arises. All cells and all secretions should fail as age advances and fail faster the more work they do. If cancer then is due to an overactive thyroid for example we should expect very many spontaneous cures, because here is a thyroid which has apparently done its full duty for fifty years suddenly doing a lot more work making old cells reproduce. This extra work should make the thyroid fail faster than the other body cells with the result that the longer the cancer grows the more hopeful the expectation would be that it would cease growing for lack of thyroid. But the opposite is the case. The longer the cancer grows the more hopeless it becomes. Therefore, the fault must be a relative failure if we are on the right track at all. Because this failure naturally would be accentuated the longer the individual lived. And failure in metabolism is also always more disastrous in the young than in the aging for manifest reasons. Thus the known fact that cancer is more rapidly fatal in the young than in the old is explainable. Also the fact that cancer is rare in the young and very common at the time of life when general failure begins. Further, relative failure would remain usually relative failure as age advances. Again relative failure is less disastrous the older the patient and we know that in the aged cancer is generally a slow process and may even last for years without appreciable change. Finally the rare but certain cases of spontaneous cure can be explained by a disappearance for some

reason of the relative failure which however must be a rare thing because it is difficult to see how naturally the relation can change much after middle life. Before discussing which gland or glands are probably at fault in a given case it is interesting to consider how the relative failure might have come about.

We know that overexercise always results in premature decay. A brain, a muscle, a blood vessel, a kidney cannot do too much work without resulting premature failure. Suppose then that a pituitary gland, for example, has for a long time been given more work than its fellow ductless glands. It will surely fail sooner than the others. Let us consider what this overwork might be. We know that the pituitary gland has a great deal to do with the proper growth and development of the skin. Now suppose the skin of the lip at a certain spot is for a long time and persistently injured by a hot pipe stem. The pituitary gland is presumably working overtime to repair this injury. Finally it can no longer do this and attend to its other duties because it is getting old and failing naturally. But it is failing faster relatively than the other ductless glands because it has had extra work for a long time. Though apparently a fanciful speculation, this is, I believe, really a factor, perhaps an important one, in the production of cancer of the lip. As to why in this case the cancer starts in the lip, it is not enough to say that it is because there has been trauma. It is common knowledge that cancer very often starts at the site of an injury, especially an injury long continued, repeated and generally mild as regards each individual act of injury. It is the repeated-drop-of-water-wearing-away-a-stone idea. This is not enough, for cancer does not always, nor indeed often, relatively, occur even at such a site. Put the two factors together, however, and the explanation seems more complete: the repeated injury and the failure of the particular ductless gland that controls the normal nutrition of the injured part. Nor is this yet enough. Why should any cell reproduce its kind at a time of life when all body cells are on the down track and physiologically dying? It seems an anomaly. Furthermore, except only the skin and squamous epithelium and possibly some columnar epithelium, which are not very common seats of cancer, none of the body cells subject to cancer can normally reproduce themselves after the period of beginning physiological death has arrived. No glandular cell once destroyed can be replaced by its neighboring gland cells at such a period. These are all highly specialized cells and have lost their original reproductive power, or rather delegated it to other special cells in the generative glands which are the real hereditary individuals. In the cells producing the spermatozoa and the ova reside the only real continuous life. All the somatic cells live as long as the individual only. They are creatures of a day, serve their purpose and die. The life is continued, reproducing, with all its inherited traits, only through these comparatively few highly specialized generative cells. And here is the anomaly: in cancer we have body cells abandoning their specialized functions and returning to the essential primitive function of all living things, reproduction; and that too when theoretically they should be physiologically dying. Therefore, there must be some factor other than failure of some ductless gland or glands, and trauma. I believe the explanation to be either one or both of two events. In the first place it seems highly probable that cancer *always* occurs at the site of cell injury for the following reasons:

1. Cancer certainly does occur often at the site of a known injury.

2. Organs which are most protected from injury are the rarest seats of cancer.

3. Organs which are most exposed to injury are the commonest seat of cancer, with one enlightening exception,—the skin.

4. The skin. But even here, remember that skin cancer is commoner by far in men than in women; men are far more exposed to skin injury than women. The reason why cancer of the skin is rare in spite of frequent injury will appear later.

5. Even those organs, apparently well protected, which occasionally are the seat of cancer may conceivably be injured, *e.g.* the kidney by stone, and the liver ducts similarly. Also it is confirmatory of this idea, that cancer of the gall bladder and the ducts is far commoner than of the liver itself.

(To be continued.)

MEASURED FEEDING FOR OLDER CHILDREN.*

BY WM. R. P. EMERSON, M.D., BOSTON,

Assistant Professor of Pediatrics, Tufts Medical School; Assistant Visiting Physician, Boston Dispensary Hospital for Children.

THE feeding of infants has become an art made possible by percentage feeding of milk and other foods, the constituents of which have been determined with almost absolute precision. Indeed exactness has been carried to such a degree that sometimes the physician's judgment is led astray by laboratory analyses. In the case of older children this condition does not obtain. In fact food is prescribed by the physician in most indefinite terms or else not prescribed at all. Such expressions as "Give the child good, nourishing food and plenty of it" or else "Be sure the child does not take anything indigestible" disposes of the whole question. Sometimes the physician may ease his conscience by adding

* Paper read and food exhibit shown at the meeting of the Suffolk District Medical Society, Jan. 22, 1913.

"Not too many sweets and no tea or coffee." It seems superfluous to state that this method of dealing with the diet of the growing child is a poor one, but it is met with so often that it demands most serious attention. Someone has well said "Why do physicians exercise so much care in prescribing drugs that are administered only occasionally and so little care in prescribing food which is taken daily." This neglect of the proper supervision of the feeding of older children is responsible for many serious diseases of early life and especially for many disturbances of the nervous system that are most difficult to remedy.

For the proper feeding of the child both physician and parent should have an adequate knowledge of food and food values. Three principal methods are in use for measuring food. In one all food is divided in portions of 100 grams and tables made out for the caloric values of each portion. This method is not readily adopted by either physician or parent, as it requires a mental readjustment of values which is a serious obstacle to its success. We buy food by the ounce or pound. All infant feeding in this country is by ounces. The change into other standards of measurements renders the method impractical except for laboratory work. A second method consists in adopting the ordinary serving as a unit of measure. This method is incorrect because what is an ordinary serving for one person is not so for another. This method also lacks an important factor present in the other two methods—namely, that of comparison, which is a great aid to memory. The third method, proposed by Irving Fisher in 1906, is called the callorie per cent. method. Prof. Fisher prepared tables indicating the amount of food necessary to furnish 100 calories of food value, such amounts being used as standard portions. For example, one slice of bread has a value of 100 calories; also one pat of butter or the lean meat in a lamb chop, or five ounces of milk or one slice of bacon. These units or multiples of units represent very closely the amount ordinarily taken at one serving, so that food can readily be served according to this plan. It gives at first hand, comparisons that help fix food values in the memory, the knowledge of a comparatively small number of which is sufficient to cover all our needs in any particular case. Sufficient information can be given in a short conversation to enable a person to raise or lower his diet 500 or 600 calories daily, which is an amount sufficient to cause a gain or loss in weight as desired.

For a child who is six to fourteen years of age, ten to twenty pounds under weight, and who continues his usual occupations, between two and three thousand calories of food per day are necessary for proper gain.

Having then a practical measure of food values, in order to make a child gain or lose body weight, the following steps are necessary: In the first place we must secure the co-öperation of the child. This can be obtained by what Dr. Morton Prince calls painting pictures. All girls want to be attractive and beautiful. They also want to do as other girls do, dance, swim and play tennis. Every boy wants to be athletic. The desire to play baseball and football can always be aroused in him sufficiently to cause him to do almost anything to gain a good physical condition for that purpose. Next there must be a sufficient control of the patient by parent or other person acting "in loco parentis" to secure a record of food taken and a regular report at stated intervals. The method I have found to work to greatest advantage with these older children can perhaps be best shown by the following case.

Thomas R., aged fifteen years, was a boy active in mind and body. He was ten to fifteen pounds under weight. Examination showed good physical development, all organs entirely normal. He was told that in order to make a good showing in athletics he ought to gain fifteen pounds. He at once said he was willing to follow any directions if he could gain, especially as he was going into a summer camp and wanted to stand well with the other boys. He was directed to keep a 48-hour list of all the food he ate and report at the end of that time. The 48-hour list showed the following points. The boy took no cereal, practically no milk, cream or butter. His average 24-hour amount was 1400 calories. He was told it was impossible for him to gain on that amount of food, that he must take at least 2000 calories. Asked why he took no butter he replied, "Why, does butter make any difference." He was surprised to know that a pat of butter was of equal value to a slice of bread. He did not like ordinary cereals, but he liked Pettijohn's breakfast food. He did not like milk but could take graham crackers and milk. Accordingly he was told to take butter and Pettijohn's daily, to take crackers and milk at 3.30 P.M. and before going to bed at night, to keep an accurate record of each day's food, and to report in a week.

At the end of the week his report showed he had followed the suggestions given and had averaged 1800 calories daily. His gain was two pounds. Encouraged by this gain, the following week he averaged 2100 calories, and gained two pounds more. The next week his average was 2180 calories and he gained three pounds, seven pounds in three weeks. At this visit he remarked "It does not matter what I take, does it, if I take enough." He said the day previous he found at night he had taken only 1500 calories, so he sat down and ate seven large figs, which raised his total to 2200. No indigestion resulted. The following week he kept no record, saying he just ate all he could and let it go at that. There was no gain in weight. The next week he did the same with no gain resulting. He then resumed keeping his record, which showed nearly 2200 calories. His gain was one and one-half pounds, making a total of eight and one-half pounds in the four weeks in which he kept his record of measured food, or an average of over a quarter of a pound per day. This boy took very little milk and no cream during this time, but was fond of nuts and figs. His average gain is what should be expected in a healthy boy. No change was made during this time in his occupation or habits. If he had not gained on 2200 calories it would have been strong evidence that he

had some organic disease, possibly some mechanical obstruction to respiration, or that he was suffering from toxic absorption, possibly from tubercular glands, or from diseased tonsils That is, the failure of a child to gain on a measured diet of 2000 or more calories per day is a valuable point in diagnosis.

The preliminary record is of importance in this method of feeding. First, it shows how much food is habitually taken; second, it shows the kind taken; third, and more important still, it shows what the child likes and dislikes making it possible to retain such foods in the diet as are agreeable to the child, simply substituting others for those that should not be taken, thus working along lines of least resistance, a most important factor in successful feeding. In the case of delicate girls, likes and dislikes, aversion to form, taste or smell, or associations of certain foods with unpleasant events, may be almost insurmountable obstacles in securing proper nutrition. Their appetites are fickle, leading them to live almost wholly on carbo-hydrate food, the proteid being far too low for proper growth. Cause and effect form a vicious cycle often made evident by this simple preliminary list.

The 48-hour record may also show mistaken ideas of parents as regards feeding. They frequently exhibit a certain pride in thinking that what does not agree with them will not agree with their children. Mistaken ideas of food values may lead to the total exclusion from the diet of many important articles of food.

During the past year a girl of fifteen came under my care because she was undersized and delicate. For ten years she had taken almost daily a large order of clear soup, the stock of which was made from the most expensive cuts of meat, the father thinking it especially nutritious. After taking a serving of such soup she ate very little else, so that her 24-hour ration was lessened by an appreciable amount. Neither parent nor physician seemed to realize that it requires nearly a quart of such soup to yield 100 calories.

Having from this 48-hour record a knowledge of the kind of food taken and its amount, it is an easy matter to increase or decrease the 24-hour intake by simple changes. For example, a girl of nine was twenty-pounds under weight. Her 24-hour amount before any suggestions were made to her about her diet was 1400 calories. Her breakfast consisted of four tablespoonfuls of cream of wheat, two teaspoonfuls of sugar, two soft boiled eggs, one roll, one-half pat of butter, and one cup of tea, making a total of 550 calories. (See table I.)

TABLE I.

		Cal.
Cream of wheat	4 tbsp.	100
Sugar	2 teasp.	50
Eggs (soft boiled)	2	200
Roll	1	100
Butter	½ pat.	50
Tea (milk and sugar)	1 cup	50—550

By adding cream to the cereal and by having the eggs scrambled, which allowed more cream and also butter, 250 calories were added to the breakfast. By substituting a cup of cocoa instead of the tea 200 calories more were added, together practically doubling the food value of the meal. (See table II.)

TABLE II.

		Cal.
Cream of wheat	4 tbsp.	100
Cream (16%)	2 oz.	100
Sugar	2 teasp.	50
Eggs (scrambled) cream 1 oz., butter	2 1 pat	350
Toast	1 slice	100
Butter	½ pat.	50
Cocoa	6% oz.	250—1000

Similar changes were readily made in the other meals, thus raising the 24-hour amount to above 2500 calories, an amount necessary to cause the child to gain from one to two pounds a week.

Such changes do not force the child to take too much food at any one meal, and, therefore, there is little danger of causing indigestion. In fact, in following delicate children with measured feeding I have seen no case of indigestion result. Children under weight seem to have a remarkable ability to digest food, taking as high as 3500 calories without digestive disturbances. While on the other hand, in the case of children who are overweight, symptoms of indigestion disappear in a remarkable manner with a diminution of the day's ration.

Measured feeding shows almost invariably that a child without organic disease is underweight because he does not eat enough and overweight because he eats too much. It is a far too common occurrence to find children taking tonics, transported to different climates, given all kinds of treatment, to make them gain in weight, when a measurement of their food shows they are taking from 1000 to 1400 calories daily, an amount too small for them to possibly gain unless actually confined to bed.

In health the question of a proper proportion of protein, fat and carbo-hydrates, namely that of a balanced diet, needs attention only in a general way, as taste regulates this in most instances. For example, bread which represents protein and carbo-hydrate, requires butter (fat) to make it palatable. Meat, composed of fat and protein, requires potato (carbo-hydrate) to please the taste. So the combination of bread and butter, meat and potato, bread and milk, represent physiological needs that taste recognizes and controls.

TABLE III.

		P.	F.	C.H.	Cal.
Cream of wheat	4 tbsp.	12	3	85	100
Cream	2 oz.	7	84	9	100
Sugar	2 teasp.	0	0	50	50
Eggs (scrambled)	2 tbsp.	68	278	4	350
Dry toast	1 slice	13	6	81	100
Butter	½ pat.	0	50	0	50
Cocoa	1 cup	34	128	88	250
Total calories		134	549	317	1000
Total grams		33	59	78	

In cases of nephritis, diabetes and duodenitis with jaundice, measured feeding applies to the different elements of food equally well as to the total quantity taken.

CONCLUSIONS.

The diet of all improperly nourished children and occasionally of well nourished children should be checked up and controlled by measured feeding.

A preliminary 48-hour list, kept without any suggestions from the physician, shows the quantity and kind of food habitually taken as well as the likes and dislikes of the child.

Changes in diet should be made gradually along lines of least resistance.

Cooperation of both child and parent is necessary for successful feeding. Both should be disabused of ideas and prejudices which interfere with proper nourishment.

The average gain on diet alone of children who are under weight should be from one-half to two pounds per week. If no gain is made, organic disturbances or toxic absorption should be suspected.

Serious errors in diet cannot be detected by asking the child about his appetite or the mother about the diet given. Food must be recorded and measured in order to show how much is taken.

Almost invariably the overweight child is overweight because he eats too much, and the underweight child is underweight because he eats too little.

Measured feeding is an important therapeutic test.

This exhibit shows about sixty common foods of the same nutritive value (100 calories). The labels have 100 small squares marked on them and the proportion of proteid, fat and carbohydrate is shown in colors, protein red, fat yellow and carbo-hydrate blue.

Liquid foods, as beef juice, orange juice, consommé, milk modifications, cream, etc., are put in bottles and preservatives added. Soap is used to represent butter and cheese. Meat and fish are represented by clay models. Artificial fruits were obtained in many instances of the proper size at shops where they are sold as favors. Dry foods, as shredded wheat and crackers, require no substitutes.

By studying the exhibit it is readily possible to visualize the amount of each food necessary to make 100 calories. For example, it requires nearly one quart of consommé or one whole bunch of celery or five ounces of milk to equal in value one pat of butter or one egg or the meat in an ordinary lamb chop.

On the right side of the upper table are three sets of graduates. The left set shows the amount of protein (60 grams) fat (40 grams) carbo-

FOOD EXHIBIT.

hydrate (250 grams) required in 24 hours by the average child six to ten years old (Koenig). The middle set shows the amounts required by an adult woman (Koenig). The right hand set shows the amount of protein (160 grams) fat (125 grams) carbo-hydrate (550 grams) taken by a child of nine years, a member of my feeding class, who was under weight twenty pounds but gaining rapidly, the total being more than double the amount taken by the adult woman.

Table I shows the breakfast of a girl aged nine before any suggestions were made as regards her diet. Table II shows breakfast modified by suggestions made to increase its caloric value. Table III shows the number of grams of proteid, fat and carbo-hydrate taken with each article of food. Table IV shows first part of a simple list of food (in preparation) to be used for practical reference in computing 24-hour amounts.

LEPROSY. SOME NOTES ON SYMPTOMS.

BY JAMES A. HONEIJ, M.D., PENIKESE, MASS.,

Penikese Island Hospital.

THE study of leprosy has been so largely devoted to the bacteriology and pathology of the disease that the many clinical aspects presented have not been emphasized. The disease has many interesting manifestations that should be studied and recorded, until such time as definite conclusions may be reached.

From practically no early symptoms, or symptoms that are indefinite and vague, the gradual progress of the disease carries with it a variety of symptoms, subjective and objective, to the final stages of the disease which are indeed complex. After the disease is definite, in both the tubercular and anesthetic types of leprosy, almost every new lesion is accompanied with some systemic disturbance. The more frequent the lesion the greater the upset to the patient, and the severer the lesion the more distressing and serious are the accompanying symptoms.

Observations made here on fifteen patients hardly warrant authoritative statements at this time, but these notes are presented for whatever value or interest they may have.

Stages of the disease can hardly be spoken of, unless it means the merging of one type into another. The disease is in the beginning insidious, and later so progressive that any attempt to define stages must necessarily be purely fictitious. So-called physiological disturbances such as headache, constipation and minor ailments, may often be viewed as part of the disease, but are not, necessarily, unless they are regular in onset or similar in most of the cases. The isolation and depressing surroundings may be responsible for the many temperamental attacks, so common among the patients here. Lack of exercise, mental torpor, national idosyncrasies and other real, or imaginary, conditions may all affect the patient. Consequently it is necessary to be careful not to assume that certain symptoms or mental states are part of the disease.

Lesions. The theory has been advanced and somewhat substantiated, that the original lesion is on the nasal mucous membrane in the form of an ulcer. The examination of every patient, with the exception of one anesthetic type case, showed ulceration or thickening of the nasal mucous membrane, some but slightly, but the majority extensively affected. The symptoms present and complained of were, difficulty in breathing through the nose, some irritation and occasional pains, discomfort during the sleeping hours and the resulting dryness of the throat.

Ulcers with a pus or watery serous discharge are, of course, the common lot of all lepers, with the exception usually of the anesthetic cases. These ulcers vary in size, are painful only in the beginning, but later may be almost entirely anesthetic, with a surrounding ring of one-half inch or more, also anesthetic and sometimes pigmented. Often and usually before the appearance of an ulcer or ulceration on the feet or hands, there is a preceding swelling accompanied with severe pain, elevation of temperature even up to 104°, rapid pulse, headache, nausea, vomiting and true chills. As soon as the swelling has become strictly localized, and an ulcer results with free discharge, the symptoms disappear, leaving the patient for several days in a depressed, weakened condition. Areas of ulceration may be in a finger, a hand, or extend from the knee to the foot and include both feet. When healing in such cases takes place, the skin is enormously indurated and largely anesthetic. The symptoms are severer in these cases than in the case of the occurrence of a

single ulcer. Alternate swelling and ulceration produce disfigurement and deformities; when the fingers are affected the finger nails become thickened, later on undergo softening, and ultimately result in the loss of the finger tips. Tremendous enlargement of the hands, forearms, ankles, feet and parts of the face are common features in the typical cases of tubercular leprosy. Constant inflammation of the skin results in its becoming thickened, forming ridges, folds and nodules, so that the features of the face become entirely changed. Such changes are gradual and slow and are accompanied by practically no pain or other symptoms.

The softening and breaking down of nodules or small swellings is fairly common. These are often slightly painful due probably to pressure and to some extent, to the involvement of the nerves. In the pus and discharges the acid fast bacillus of leprosy and a micrococcus are always found. Without being visible to the eye there may be numerous small nodules or infiltrations underlying the skin, which are only discovered when the hand is firmly stroked along the parts.

Bullae or blebs may occur naturally in the course of the disease or may be induced by friction or injury to the skin, as by scrubbing or washing. These have occurred only on the hands and feet. The bullae vary in size from a dime to areas covering the whole surface of a finger, are considerably elevated and filled with a clear amber colored fluid, which contains both the leprosy bacillus and a micrococcus. These bullae have occurred only in the tubercular type of cases; they occur rapidly and may last several days, leaving an inflamed, watery surface, which is usually easily amenable to treatment. An eruption occurs at irregular intervals over the back, shoulders and chest, similar to the rash that accompanies digestive disturbances, and not unlike that of ivy poisoning. It usually lasts the better part of a week, and is accompanied by true chills in most cases, elevation of temperature and pulse, malaise, vague pains, headache and depression. This phenomena has been alluded to as a malarial condition, but in truth does not in any way resemble typical malarial fever attacks. An examination of the blood does not reveal the malarial parasite or bodies analogous to them.

In the nature of an eruption are the occurrences of pustules containing both the leprosy bacillus and a micrococcus. These pustules may occur singly and later form an ulcer, may coalesce, or may occur in crops, develop, break down and heal, leaving slightly pigmented spots as a result. In two cases this occurred all over the limbs, upper and lower, and continued for nearly two months. The attack was accompanied by fever and some pain, and resulted in numerous pigmented areas. In both the tubercular and anesthetic cases, small pigmented spots occur without apparently preceding open, active inflammation or ulceration. At or near the lesions, the skin may be excessively dry and scaly, or it may be moist and secretive, and is most typical on the hands, legs and feet.

In the nasal secretions, discharges from ulcers, fluid from bullae and in the pus from pustules, the acid fast bacilli of leprosy has been found.

Pain. This symptom varies so considerably in all patients that it is probably of little value. It differs in degree during certain phases of the disease and the patient's general health has much to do with it. The difficulty in ascertaining the degree of pain is increased by anesthetic and hyperesthetic areas. Neuralgia or so-called rheumatic pains of a very indefinite origin are common, excepting with the anesthetic cases. These pains are most frequently complained of at night time, severer in cold weather, of varied duration, and apparently not associated with other symptoms. Often during a febrile attack such neuralgia-like pains are present but are not to be confused with the same pains as stated above.

Localized pain with swelling and inflammation usually precedes an ulcerative process. It may be totally relieved when there is a free discharge and subsidence of the swelling, or it may lessen and be of longer duration. The pain is often so severe that sedatives and opiates have to be prescribed. The accompanying symptoms have already been mentioned.

Pain as a result of nerve involvement in leprosy, such as occurs with the optic nerve, will not be dealt with here. Pain, associated with all the signs of inflammation of the eyes and eye lids, is usually severe, the itching, burning and lacrymation being especially troublesome, and does not respond easily to treatment. The eyesight is affected only after a long time, when the inflammation and its after results, affect the deeper tissues of the eye. Headache, unless occurring with or during febrile attacks, are of so obscure an origin, that its analysis is useless.

Burning and itching are common complaints. Burning or warm sensations are usually so vaguely described and so indefinitely localized, that they may simply be mentioned here as a symptom commonly spoken of in leprosy. Itching and biting sensations are not rare and are usually referred to the back and abdomen; they are generally associated with a dry condition of the skin. The itching is readily relieved with salves or ointments, and consequently is probably not indicative of actual peripheral nerve involvement.

Sweating. It has been stated that sweating is a symptom common to leprosy, but from the cases studied here it has been impossible to determine it as such. The systemic disturbances are so marked in the advanced stages of the disease, when nervous symptoms, exhaustion, weakness and the anxiety of the patient are all present, that it is questionable indeed whether we should view sweating as a symptom of the disease. Sweating, as is well known, is concomi-

tant with chronic exhausting diseases, such as tuberculosis, and it is in all probability the same with leprosy. In leprosy sweating often follows the severe chills during the febrile attacks when the patient is certainly in a low physical condition.

Chills. The patient may at irregular intervals suffer from true chills, as has already been mentioned, and at such times as active inflammatory changes take place, and tissues break down, and ulcers occur. It is possible to consider such chills as the result of the softening and breaking down of nodules and other areas of infiltration and that the bacilli, or their toxic properties, are then set free and taken into the blood stream with the resulting disturbance. Chills with septic infection, typhoid and malaria, are of course well known, and the analogy here is not at all far drawn. These chills are often severe, with great systemic disturbance, the patient is prostrated, the temperature may rise three or four degrees or suddenly drop to subnormal, with the pulse essentially agreeing with the temperature. The chills last from a few minutes to the greater part of an hour, and may occur as often as four or five times in twenty-four hours; or again there may be a single chill, without recurrence for months.

Apart from the occurrence of true chills, chilliness is often a complaint, and more marked with the patients who are anemic. Chilliness may be complained of on the brightest and sunniest days and when the patient is free from all other symptoms and is not associated with digestive or intestinal troubles. The question of the blood picture during true chills will be dealt with in another note. In the anesthetic cases here, no chills or feeling of chilliness has been noticed, it being most noticeable in the far advanced tubercular leprosy patients.

NOTES AND CONCLUSIONS.

A. When the disease is advanced the patient's health varies daily; he feels exceptionally well one day and the next presents every symptom and appearance of a seriously sick person.

B. In comparison to the severe symptoms and general appearance of the patient, physical examination will reveal nothing. Lungs and abdomen are normal, and with the exception of a soft systolic murmur over the precordia, the heart is normal.

C. During eruption the skin is usually hot and dry.

D. Extreme mental depression at irregular intervals and nervousness are characteristic of every case.

E. Ulcers may heal rapidly and continually, or, as is seen in one or two cases, they become chronic and refuse to respond to treatment. Medicinal treatment varies in each case; in leprosy this fact is particulary accentuated.

F. The clinical symptoms of leprosy, although somewhat confused and often indefinite, are, nevertheless, correct symptoms of the disease and in the care and treatment of leprosy patients, are to be carefully observed and seriously considered. The consideration of the pulse, temperature and blood are so important and instructive, that a more careful study is being made and will, in all probability be reported in the future.

In conclusion I wish to thank Dr. Frank H. Parker, superintendent Penikese Island Hospital, for his kindly advice and criticism in the preparation of this paper.

INSTITUTIONAL DENTISTRY: METHODS: RESULTS. REPORT NO. 2.

BY FREDERICK A. KEYES, D.M.D., BOSTON.

In the issue of the Boston Medical and Surgical Journal of July 25, 1912, there was printed an article entitled "Institution Dentistry: Methods; Results," in which I submitted to the medical profession a report of dental work done at St. Vincent's Orphan Asylum, Boston, and its relation to the infectious diseases of childhood. This statistical report, showing the great decrease of infectious diseases at the orphanage after the establishment of a dental infirmary, amazed even the most enthusiastic propagators of oral hygiene.

Owing to the frequent inquiries regarding the progress of the work since the publication of this article and the many urgent requests for further information, I have deemed it expedient to submit the following report of the last 18 months' work.

The number of children at the Asylum January 1 1912.....	227
Children received during the year	76
Children cared for by the Home during the year.....	303
Children taken out by relatives...	121
Children in Asylum Jan. 1, 1913..	182

The system of dental work remains the same. The inspection of the children monthly to see that they are keeping their mouths clean and the admonition of the few that are negligent in this respect has been rigidly observed. The tooth brush brigades, led by the older girls, are accomplishing the desired results, *i.e.* teaching the younger children how and when to brush their teeth, so that the habit thus formed in childhood may continue throughout life. A nitrous oxide oxygen apparatus has been installed and found to be a most valuable, though expensive, adjunct in the elimination of pain.

The following statistics contain the record of work done for the past 18 months. For those who have not read the first article, statistics for the first 18 months are included,—with a partial account of the money expended for materials necessary during that period:

	Nov., '10 to May, '12	May, '12 to Nov. '13
Total number of different patients examined	349	303
Total number of cleanings	272	350
Total number of cement fillings	25	45
Total number of amalgam fillings	72	76
Total number of cement amalgam fillings	69	60
Total number of temporary fillings	130	180
Total number of oxphas cu. fillings	9	57
Total number of teeth extracted (temporary)	290	102
Total number of teeth extracted (permanent)	131	51
Total number of abscesses opened	42	21
Total number of gums cut for permanent teeth	19	9
Total number of plastic operations	3	0
Total number examined and treated	1421	1254
Total number of fillings (including temporary)	315	418
Total number of teeth extracted (including temporary)	421	153
Total time spent (hours)	210	190

Account of Expenses.

Initial cost (chair, engine sterilizers, brushes, etc.)	$125.00	
Supplies for 18 months	66.63	
Nitrous oxide oxygen apparatus (initial cost)		$86.15
Supplies for 18 months, including gas and oxygen		75.00
Totals	$191.63	$161.15

A study of the above tables will show the great number of teeth filled and the few extractions necessary in the last 18 months in comparison with the preceding 18 months. It is hoped that, after all cavities in the mouths of the permanent inmates of the Asylum are filled, the future work will be solely prophylactic treatment (cleaning). But every year there is an influx and exit of from 75 to 100 new children. Therefore, extraction and filling will necessarily be the first important factor. After filling and extraction are completed, the cleaning of the teeth every three months by the dentist and daily by the patient is expected to prevent future caries in the children's mouths. Contrary to the usual routine, dental repair work is done on the older girls in preference to the younger ones, since the older girls are liable to leave the Asylum first and it is our desire to send them out into the world with mouths free from all carious cavities. Odontalgia has been practically eliminated.

Below is printed a table containing the number of infectious diseases occurring at the Home in the last 36 months, together with statistics of previous years.

RECORD IN REGARD TO INFECTIOUS DISEASES.

	1907 1908	1908 1909	1909 Nov., 1910	Nov., 1910 Apr., 1911	Apr., 1911 May, 1912	May, 1912 May, 1913	May, 1913 Nov., 1913
Diphtheria	6	2	1	0	0	0	1
Mumps	8	3	10	4	0	0	0
Scarlet fever	17	8	12	8	0	0	0
Pneumonia	3	5	4	6	0	0	0
Measles	24	50	40	25	0	0	6
Tonsillitis	19	16	8	3	0	0	0
Whooping cough	7	2	2	0	0	0	0
Chicken pox	15	17	10	6	0	0	0
Typhoid	0	0	0	0	0	0	0
Croup	4	0	0	0	0	0	0
Spinal meningitis	0	0	0	0	0	0	0
Scarlatina					0	0	0
Bright's (acute)						0	0
Hemorrhage							0
Tuberculosis of eye					1		
Tuberculosis of lungs					1		
	103	103	87	52	2	0	7

From the above data it may be seen that in the last 36 months only 7 cases of infectious diseases have occurred at the Asylum. Of these 6 were measles, one of which was contracted before or immediately after admittance to the Home. The disease spread to 5 children, permanent inmates of the Asylum. The mouths of all six patients were carefully examined and found to be in need of dental treatment. Whereas in previous years 40-50 children were stricken down with measles this year only 5 children contracted the disease. The one case of diphtheria also occurred in a new girl. Examination of her mouth showed great need of dental work.

What is the cause of this elimination of disease from St. Vincent's Orphanage immediately after the beginning of dental work and the continuing of this immunity for a period of three years? Dentists need no longer claim to be great prophylactic agents in the field of medicine; for the above statistics demonstrate convincingly the immunity acquired from infectious diseases of childhood after the proper treatment of the child's oral cavity.

For many years dentists have spent much time and effort in compiling and presenting statistics showing the relation existing between carious teeth and infectious diseases of childhood. In many large cities these efforts are bearing fruit. It is, however, hard to understand why there should be so much delay in some parts of this country, especially in Boston, in meeting this problem. At present there exist in other municipalities many methods of handling the public school question, most of which are still in the experimental stage but are nevertheless accomplishing a great deal of good. In Boston, however, the dental question is most unsettled. Spasmodic attempts, most of them theoretical, to remedy this defect in the past have been unsuccessful. At present, even with the new Forsyth Dental Infirmary, the results predicted will be merely scraping the surface. The

Forsyth Dental Infirmary in full working order will be able to handle only a part of the carious cavities now existing in the mouths of the Boston public school children. The good that is to be obtained from this great philanthropy cannot be over-estimated; but without the co-operation of the City of Boston and the medical profession the desired results will fall short.

Establishment of school dental clinics working harmoniously with the Forsyth Dental Infirmary, to my mind, is essential in handling the 100,000 children in the Boston public schools. The 64 chairs at the Forsyth Institute are inadequate to meet the needs of the public school children.

Paid dental inspectors should be appointed by the City after competitive examinations similar to those now in vogue for the school physicians. To permit school nurses to act in the capacity of dental inspectors is indeed a sad commentary upon the importance of this great field of medical science. Nurses are no more competent to judge between dental conditions needing immediate care than they would be in diagnosing adenoid or tonsillar diseases.

Paid dental inspectors are necessary to handle the public school question. Even though the time has not yet come when school dental infirmaries are to be established necessitating dental inspectors in the public schools, even now under the present conditions the Forsyth Institute is in dire need of inspectors in the schools to send them cases needing immediate treatment.

Dentists are very apt in their over enthusiasm upon this subject to momentarily offer their services free to the municipalities. But no work of any great value requiring all a man's working hours was ever well and properly done without monetary compensation.

Progress in school dentistry must come. Further agitation should not be necessary. Physicians should co-operate with dentists and school authorities to demand that steps be taken to eliminate the present conditions existing in the mouths of the public school children.

A FURTHER REPORT ON THE MAYO-GILLIAM OPERATION FOR RETROVERSION OF THE UTERUS.

BY HAROLD W. BAKER, M.D., BOSTON,

Surgeon to Out-Patients, Free Hospital for Women, Brookline, Mass.

As pointed out in a previous paper,[1] the best method for the treatment of retroversion of the uterus, is the operative treatment, wherein the Mayo modification of the Gilliam technique is used. The steps of this operation have been gone over in the previous paper, and we do not need to refer to them again.

The three classes of operations performed by the best authorities for retroversion, may well be described here with their results. They are:—

1. Hysterorrhaphy, which may be divided into two classes, namely
   a. Suspension.
   b. Fixation.
2. Intraperitoneal shortening of the round ligaments.
3. Extraperitoneal shortening of the round ligaments.

By suspension, we mean the mere suturing of the uterus to the peritoneum. This method has proved by long and extensive use to have too many recurrences to justify the continuance of this attempt to cure. This fact was shown in the first paper[1].

By fixation, we mean the suturing of the uterus to the abdominal fascia. This procedure, on the other hand, has demonstrated that it actually does accomplish the purpose for which it is done. The objection to fixation is not failure to do what it purports to do, but that complications from it[6] are too serious and numerous to warrant doing it during the child-bearing period. There is a fault common to both suspension and fixation, in that they are not anatomically justified, for the uterus is normally a movable organ, and they both attempt to immobilize the uterus.

We believe that the intraperitoneal shortening of the round ligaments, as done by Baldy[4], Webster,[7] Coffey[3], and others, is giving much better results than it did five to ten years ago, when we saw a recurrence in thirty-one out of thirty-five cases[1]. We object to this procedure, however, as it utilizes the weakest part of the ligaments to do the heaviest part of the work. The chance for recurrence is still very great.

The extraperitoneal shortening of the round ligaments, the Alexander type of shortening[2], is good, but it has a moderately high percentage of failure. The reason for this percentage[1], is due in all probability to the fact that adhesions of the uterus are not easily recognized even when the patient is fully anaesthetized. The operation utilizes the strongest part of the ligaments, and it does not interfere with the normal motility of the organ. There is one distinct disadvantage to this operation, and that is that the surgeon is unable to examine the other abdominal organs.

We have begun to emigrate from the old idea that the best surgeon is the one who makes the smallest incision, and who does the least exploring. The patient is apt to embarrass her surgeon, a year or two later, if she comes back to him (or to another), with other abdominal trouble which might have been found and relieved by abdominal exploration at the time of the former operation. We prefer to know that the abdomen is completely negative, rather than to go on any assumption. The knowing adds nothing to the risk of the operation, and it adds much to the mental comfort of the patient, and

incidentally of her surgeon. We discard the idea that because a patient has one apparent trouble, she may not have another less apparent one.

The Mayo- modification of the Gilliam operation[5] for retroversion, comes nearest of all methods, to restoring the uterus and its supports to their anatomically normal position. It does this, moreover, by utilizing the strongest part of the round ligaments. It also permits the free exploration of the abdomen. At the present time, from personal knowledge of the conditions of the pelvis of all the cases cited both in this paper and in the previous one,[1] we believe that the after results of this technique are as good if not better than those of other operative procedures. These cases are taken from the clinic of The Free Hospital for Women, Brookline, Massachusetts, and from private practice. In support of our beliefs, we desire to submit the following table of cases, dividing the cases into groups of six months each, as regards the elapsed time since operation.

TABLE OF RESULTS FOLLOWING THE MAYO-GILLIAM OPERATION FOR RETROVERSION.

No. Mos.	No. Ops.	Children.	Pregnancies.	Recurrences.
0-6	25	0	0	1
7-12	24	0	0	0
13-18	28	0	0	0
19-24	11	1	1	0
25-30	16	3	3	0
31-36	21	1	1	0
37-42	6	0	0	0
43-48	13	3	3	0
49-54	3	0	0	0
55-60	21	2	2	0
61-66	2	2	2	0
67-72	1	0	0	0
Totals	171	12	12	1

A study of the table shows clearly that the uterus suffers no inconvenience on account of the Mayo-Gilliam operation. None of the women have had any further trouble referable to the uterus, and the ten who have had one or more pregnancies, have had perfectly normal labors in every way. Two of the women have each passed through two uneventful pregnancies, their labors presenting no abnormal features. Putting it in percentages, we find 7% of our cases have gone through pregnancy without any trouble, and as they all were free from complication of any kind, 100% of the pregnant cases had no trouble from the operation. We have had only one half of one percent of recurrence. This one recurrence is easily understood, as the patient developed the retroversion about three months after operation, and we believe that it was due to a cutting out of the suture material used. Later, she was again subjected to a laparotomy for another trouble, and a second Mayo-Gilliam performed, and this time no recurrence took place.

In conclusion, we must, with these results before us, reaffirm our statement that the Mayo-Gilliam operation for retroversion has proved to be the best of any from anatomical, functional, and curative viewpoints.

We wish to thank Dr. Donald V. Baker for his kind assistance in the compiling of this paper.

APPENDECTOMY IN A BLEEDER. BLOOD IN VOMITUS AND STOOLS. MASSIVE HEMATOMA AND ECCHYMOSIS. RECOVERY.*

BY TORR WAGNER HARMER, M.D., BOSTON,

Assistant in Surgery, Massachusetts General Hospital; recently Alumni Assistant in Surgery, Harvard Medical School, and Assistant Surgeon to Infants' Hospital.

In the early evening of August 11, 1913, I saw Mr. H——, a travelling salesman of 25.

Three days before he felt "logy" and after a hurried luncheon of crackers and cheese he experienced a sense of fulness and distention of the upper abdomen which persisted throughout the afternoon and evening but did not prevent sleep. The following morning he had pain in the epigastrium but no nausea or vomiting. In the afternoon the pain shifted to the lower abdomen and his head began to ache. Yesterday he felt feverish, and pain in head and lower abdomen persisted. In the evening a dose of salts was taken. This morning he felt better, headache had gone, only tenderness in right lower quadrant remained. This afternoon fever and pain in lower abdomen returned. There has been some nausea but no vomiting. The pain has become acute. Bowels had moved daily till today, movements painless and without blood. No difficulty with urine. No cough or pain in chest. He had never previously had any "indigestion." A year ago he was under my care for subdeltoid bursitis. One brother had been operated for appendicitis in the presence of peritonitis and had died.

A tall, spare youth with flushed cheeks, hot skin, dry lips, and tongue with slight white coat. Pupils equal and reacted equally to light. Heart and lungs showed nothing abnormal. Abdomen was flat, not distended, tympanitic throughout with much tenderness and spasm in right lower quadrant but no palpable mass. Liver, spleen, and kidneys not felt. No costovertebral tenderness. Lateral compression of lower costal cage not painful. No inguinal hernia. Genitals negative. Knee jerks equally active. No ankle clonus. No edema or jaundice. Questionable tenderness by rectum high on right. Temperature 101. Pulse 100. White count 16,000. Urine, high

* Reported before Surgical Fortnightly Club, Nov. 25, 1913.

color, clear, acid, sp. gr. 1022, slightest possible trace of albumin, no sugar. Abdominal pain was relieved by lying down with right leg drawn up.

A diagnosis of acute appendicitis was made and two hours later he was on an operating table under ether (preceded by nitrous oxide) with pin-point hemorrhages over the freshly shaved pubes. My assistant's apology was dismissed with pleasantry about hospital razors. A 3½-inch incision was made over the right rectus muscle midway between umbilicus and pubes. The anterior sheath of the rectus cut, the muscle bluntly divided longitudinally, and the deep epigastric picked up either side of the wound, cut, and double tied. The wound was a pool of blood. A number of vessels were picked up but as the ooze seemed general a sponge was laid against either side of the wound and held by retractors. The peritoneum was opened without incident. The appendix was felt behind the cecum. The cecum was raised. Although the manoeuvre was gentle, a patch of hemorrhage immediately developed in the wall of the cecum and tongues of blood spread peripherally apparently just beneath the serosa. A short, swollen, injected, unruptured appendix was delivered rather readily, after breaking a few fine, fresh adhesions and snapping and cutting an old band. The meso-appendix was clamped and cut in sections from tip to base. The right quadrant was then filled with blood. This was sopped out, the appendix tied off, cut, and the stump touched with carbolic acid and alcohol. The clamped portions of meso-appendix were tied off. Still the mesentery-line oozed smartly. Several extra ties and a couple of interrupted sutures checked but did not stop the ooze. The abdomen was closed tightly in layers, the peritoneum continuously, the fascia and skin interruptedly. A few through-and-through sutures down to the peritoneum had been placed. It was necessary to sponge continually while closing the belly wall. Everything bled. Every stitch hole was a new bleeding point. Anticipating a hematoma in the wound, several folded-pieces of gauze were placed over it and held snugly against it with tightly-placed adhesive straps. A large pad and firm binder completed the dressing. Although considerable blood was lost, the character of the pulse was always fair, never alarming.

To keep blood pressure down he was given no fluids during the night and two small doses of morphine to combat restlessness. The improvement was remarkable. The next morning (8 A.M.) the pulse was 68 and of good quality. Liquids without milk were started; 33 ounces were given up to midnight, he had two stools after an enema, and voided 18 ounces. At 2 P.M. he vomited 2 ounces of very dark brown liquid, very similar to the vomitus of peritonitis. Vomiting of similar character occurred at 4.30 P.M. 12 ounces, and the next day 4.45 A.M., 7 ounces, 12.30 P.M. 16 ounces, 5.30 P.M. not measured. The stools were all of old blood and occurred as follows: August 12, 4.30 and 5.00 A.M. after enema, 12.15 P.M. voluntary, 4.45 P.M. after enema, 6.45 P.M. voluntary, 9 P.M. voluntary; August 13, 3.30 A.M. after rectal tube. The temperature rose to 102 and pulse to 90 August 12, 4 P.M. Removal of the dressing revealed the incision elevated on a rounded prominence about 5 inches long and 2½ inches wide of purplish blue color and of firm consistency, evidently a massive hematoma. Extending from this to edges of the pad was a paler ecchymotic field. At the edges and just beyond the edges of the pad the ecchymosis was more intense. Extending from this field were strips of ecchymosis marking the edges of the adhesive straps. These extended well into the flanks. Beneath the straps there was no discoloration. The abdomen was soft, tympanitic, and peristalsis was evident by auscultation. Another examination of the urine was negative (slightly high color, clear, acid, no albumin, no sugar). The vomiting was always of the expulsive rather than the overflow type. For 24 hours he was denied anything by mouth, given 8 ounces of salt solution by rectum every 4 hours and morphine subcutaneously to keep quiet. Vomiting promptly ceased. For eighteen hours longer the rectal salt was continued with the addition of 3ii soda bicarbonate and 3 ounces of water with 3i of soda bicarbonate was given by mouth every 2 hours to combat the acidosis which might well occur after practically 3½ days of starvation. The soda and enemata were then omitted and soft solid diet immediately instituted. Convalescence was henceforth uneventful. The ecchymosis gradually worked down onto the penis, and became general over the abdomen, and then began to fade. From the discovery of the hematoma the wound was covered daily with alcohol dressings. The stitches were removed on the seventh day and the hematoma, then much reduced in size, evacuated through a director thrust. The wound stayed clean, oozed serum for several days, and closed. He was up and about the room on the twelfth day and discharged to his home on the fourteenth day. I saw him one month later (Sept. 20). He was looking and feeling well. The wound was strong and solid and the ecchymosis only very faintly evident. Seen again on October 12 in perfect health. Reported by telephone November 30 that he was in excellent condition.

Just before his discharge from the hospital I obtained the following history which I had failed to obtain before operating.

About three or four years ago had two or three teeth extracted. Bleeding continued for three days although he made several trips a day to the dentist who used various astringents and packings.

Two years ago he fell on the ice, striking his hand and splitting open the tip of one of his fingers about one-quarter inch. This bled for two days despite bandaging and stopped only after suturing.

Whenever he cuts himself shaving, he bleeds much more than most people, he thinks, and it may even keep him from attending his business.

In his family history I find no bleeders. Father, mother, two brothers, and one sister are living and well. One brother died at 22 of peritonitis following appendicitis. One brother died at 11 months of some spinal trouble.

Reviewing the events of the convalescence we do not find the picture of peritonitis or intestinal obstruction, certainly not of acute dilatation. Although the appearance of the vomitus was that of peritonitis it was always of expulsive character. Again the bowels moved spontaneously several times, gas was voluntarily passed and peristalsis was always evident by auscultation. Again the belly was comparatively soft. It was certainly not spastic, even about the wound. True, the temperature and pulse rose (temperature 102, pulse 90) but came down to 99 and 80 within 24 hours with general improvement. The expulsive character of the vomitus, the evidence of peristalsis by

auscultation and a few movements would not be inconsistent with obstruction. The number and bulk of the movements and lack of distention or tenseness of abdomen argue against this diagnosis. The evident explanation is as follows. Haemorrhage into bowels (appearance of stools and vomitus) and absorption of extravasated blood (rise of temperature and slight rise of pulse). At operation gentle traction of caecum to expose appendix caused haemorrhage into wall of caecum and probably from mucosa. Just before closing abdomen it was seen that there was no Lane's kink or Jackson's membrane. The pyloric end of the stomach, the duodenum and the gall bladder were felt and were apparently normal. This added manipulation, although usually not appreciably harmful, may have amounted to trauma in this case. Although there may have formed a hematoma in the region of the caecum, it seems unlikely that the rise of temperature was due to its infection, although readily possible in the bed of an appendix subject to only catarrhal inflammation; for the temperature dropped within 12 hours to 99 and rose only once again to 100.

I am led to place this case on record for two reasons.

First: As a reminder of this as a serious surgical complication and as a reminder of what I believe very common negligence, failure to make inquiry about bleeding in obtaining the history, especially in acute conditions.

Second: On account of the unusual symptom complex: rise of temperature and pulse, vomitus of the appearance of that of peritonitis but expulsive in character, belly without spasm and comparatively soft, stools of old blood and some copious and voluntary, and massive hematoma and ecchymosis of abdominal wall.

Medical Progress.

PROGRESS IN OPHTHALMOLOGY.

BY EDMUND W. CLAP, M.D., BOSTON.

TUBERCLE OF THE CHORIOID.

Marple[1] has reported on tubercle of the chorioid in tuberculous meningitis. From 1908 to 1911 there were 128 cases seen by him, the percentage showing tubercle of the chorioid not exceeding 5%. Carpenter and Stephenson had found it in 50% of their cases. For the first six months of 1912 thirteen cases of tuberculous meningitis in children entered the hospital and were examined under atropine and with an electric ophthalmoscope several times a day, and in every case tubercles of the chorioid were found sooner or later. Cases negative one day would show them the next day, and even a case without them at one examination would show one or more four hours later. He found small miliary tubercles, round or oval in shape, rarely irregular, of a greyish or grey-white color, usually without any pigment, with a moth-eaten edge, and varying in size from the breadth of a primary retinal vessel to a mass the size of the optic papilla or larger. In the greater number of cases they are limited to one eye and usually not far from the optic disc. Papillitis was found in four out of nine cases, and in three of these it was double. The author has never seen any exudation on Descemet's membrane in cases of tubercle of the chorioid.

VAN LINT'S OPERATION.

Van Lint[2] has proposed a method of avoiding prolapse of the iris after cataract extraction, which has been more or less tried by other operators this year. Before making the incision the conjunctiva is detached corresponding to the upper half of the corneal limbus and dissected from the sclerotic upwards 8 or 10 mm. A silk suture is inserted into this loosened conjunctiva on each side and the lower end of each suture passed through the conjunctiva below the horizontal meridian of the cornea, so that when they are tied after the extraction, the detached conjunctival flap glides in front of the corneal wound and covers about the upper fourth of the cornea. After the regular extraction the sutures are tied and the threads cut off close to the knots. The conjunctiva gradually retracts and from the second to the fifth day it has receded from the cornea. This procedure does not lead to any nutritive change in the cornea nor to astigmatism.

SENILE CHANGES IN THE EYE.

Attias[3] has investigated senile changes found in the human eye. Most authors, including Parsons, attest the presence of fat in the arcus senilis, but Fuchs called it a hyaline degeneration, and Leber traced calcium salts in the arcus. Attias with modern methods has shown that neither hyaline substance nor lime salts are a possible cause of the opacity, and he also proves that the substance reacts in all respects like fat. The author found fat granules even in the corneal epithelium and in Bowman's membrane. The middle strata of the cornea are as a rule the last to be affected by the deposition of fat. In some cases even the endothelium of Descemet's membrane had fat droplets in the protoplasm. Vollaro has found fat in the anterior part of the sclera in old eyes. Takaysu has confirmed this. The iris of aged persons may show partial or complete disappearance of the pigment layer at the pupillary margin and the tissue here and behind the sphincter may change into a hyaline mass. The fibres of the ciliary muscle are much thinner than in young subjects. The interfibrillar tissue is increased in amount and may

show a little fat. The ciliary processes show much increase in connective tissue and this may assume a hyaline aspect. In true gerontoxon lentis the capsule of the lens is normal, but the peripheral fibres have vacuoles in and around their nuclei and finally large spaces form and numerous fat drops. The eye muscles show a greater variation in size of fibres than in youth and the nuclei are often rounded and irregular. Fat is found here, too. In the nerves of the anterior segment of the eye degenerated fibres are more abundant in age than in youth.

MICRO-ORGANISM OF PARINAUD'S CONJUNCTIVITIS.

Verhoeff[4] has described a filamentous organism which he believes is the cause of Parinaud's conjunctivitis. The disease has been thought to be of animal origin and infectious, though no specific micro-organism has been hitherto found. Verhoeff and Derby have shown that the lesions in Parinaud's disease are histologically characteristic. While some recent observers have contended for the tubercular origin of this disease, their cases did not show the typical histology and were probably cases of conjunctival tuberculosis. The author has examined twelve cases histologically. Each was monocular and showed conjunctival granulations with areas of cell necrosis and enlargement of the preauricular lymphatic gland. The characteristic feature is the occurrence of focal areas infiltrated with endothelial phagocytes in various stages of necrosis. These cells are not close packed but discreet. There is a relatively small proportion of lymphoid and plasma cells in the areas but almost no pus cells. These areas, .3 to .5 mm. in diameter, are usually just beneath the epithelium. Surrounding the areas of cell necrosis the tissue is densely infiltrated with plasma cells. These twelve cases clinically as well, were cases of Parinaud's disease. By the method of fixation and staining detailed by him the author has demonstrated in the areas of cell necrosis in sections and also in tissue scrapings a filamentous organism occurring in masses. A high power shows these masses composed of intertwined delicate, faintly staining, singly contoured filaments. At almost regular intervals along the filament round dots occur which stain intensely by the modified Gram method. These are never exactly centered in the axis of the filament but project beyond its surface. The dots are seldom all of one size on one filament. In tissue scrapings filaments 30 micra in length may be seen. In eleven out of twelve consecutive cases these were found and in the one case the material was insufficient. The absence of any other demonstrable micro-organisms, their unusual character, their great abundance and the fact that they were so situated as to explain the lesions make it reasonable to regard them as the cause of the disease. Since no branching of the filaments could be made out they may be classed for the present as a leptothrix.

VISUAL SYMPTOMS OF SINUS DISEASE.

Fridenberg[5] calls attention to the visual symptoms of accessory sinus disease. Many symptoms of progressive sinusitis are ocular or orbital. We have nerve irritation in the form of reflexes or from direct action of toxic substances, mechanical pressure of hyperemia. So we get lachrymation, clonic or tonic spasm of the lids, fleeting edema, transient conjunctival or scleral injection, miosis, and occasionally spasm of accommodation. We may have transient rise of intraocular tension, with prodromata, or an actual attack, of acute glaucoma disappearing promptly under treatment of the sinus. Fleeting pain of eyeball, brow or temple, or even severe pain of a hemicranic type may belong here. Accommodative, conjunctival, muscular or retinal asthenopia is not infrequently found in cases of long standing accessory sinus disease. In scintillating scotoma the sinus should be examined. Of course mechanical involvement of nerve, muscle or eyeball is well known. The sinuses should always be considered in retrobulbar neuritis, especially posterior ethmoid or sphenoid disease and the optic nerve involvement may be not only mechanical but a toxic one analogous to tobacco or lead. In a large series of cases of disease of the posterior sinuses Van der Hoeve[6] noted an invariable enlargement of the blind spot.

ANAPHYLAXIS IN OPHTHALMOLOGY.

Szily[7] treats of anaphylaxis in ophthalmology and says that experiments have been made in two directions. One group busies itself with the question of the antigen working of various tissues of the eyeball in general anaphylaxis. Another question of greater practical importance is whether it is possible to bring the entire organism into a state of anaphylaxis from the eye. It is possible with heterologous proteid, but doubtful if it can be done from an animal's own tissues. So far, anaphylaxis has been suggested as playing a part in two eye diseases, sympathetic ophthalmia and interstitial keratitis. Elschnig[8] in a series of studies explains the nature of sympathetic ophthalmia by assuming that in severe lesions of the eyeball or in severe spontaneous inflammations of the uveal tract, uveal pigment in antigen form is absorbed and brings about a sensitization of the entire organism to this antigen. Then there needs only a pathological process with even slight pigment changes in the other eye, and a local anaphylactic reaction ensues. The sensitization from absorption of antigen in the first eye acts not only on the uvea of the second eye but also on the retained uvea of the first eye and keeps up a continuation of the disease, which spreads through the uvea under the same pathological picture as in the second eye. Von Hippel has offered several grave objections to this view, however, but it affords grounds for interesting speculations.

Peters[8] refers to the occasional disturbance of hearing in sympathetic ophthalmia and the possibility that the normally present pigment in the labyrinth plays a rôle therein. He shows that the deafness, in some of these cases at least, is not due to meningitis. Szily quotes Wessely's experiments on rabbits, of injecting one or two drops of sterilized inactivated horse or steer serum into the parenchyma of the cornea near the upper limbus. Two different effects followed; usually there was no reaction and the eye remained free from irritation, or after twelve to fourteen days there was a clouding of the deeper layers of the cornea above and deep vascularization. This reached its height in fourteen days and disappeared completely. If one injected foreign serum into the other eye at the time of this attack the characteristic inflammation appeared in this second eye, too. Arisawa and Szily found that if after fourteen days the first cornea be injected again whether the reaction had occurred or not, within twenty-four hours a marked infiltration of the deep layers over the whole cornea followed with signs of iritis. A third series of experiments began with the injection into one cornea and fourteen days later 4 c.c. of the same serum was given intravenously, at once the pupil of the injected eye contracted and remained so for some minutes, and then within twenty-four hours a typical picture of interstitial keratitis developed. Fourthly, an intravenous or subcutaneous injection of the serum followed in two weeks by an injection into one cornea gave in twenty-four hours the characteristic reaction. After a theoretical discussion of these results the author concludes that anaphylactic processes are concerned in parenchymatous keratitis and that this may throw some light on its occurrence after trauma. Analogous types of reaction have been observed in injection of serum, lens albumen or uveal tissue into the vitreous. The author thinks that the adjustment to or increased sensitiveness to chemical poisons differs so entirely in its nature that it should not be considered an example of anaphylaxis. Anaphylaxis or immunity is due only to antigen bodies and has a symptom complex independent of the sort of injected antigen and too hypersensitiveness to toxin or poison cannot be transferred to a normal animal through the blood serum as can anaphylaxis.

CHRONIC UVEITIS.

Fuchs[10] has made a very important study of chronic uveitis, the pathology of which he has been working on for a number of years. This covers the cases not due to syphilis, tuberculosis or sympathetic inflammation. Chronic uveitis includes iritis, iridocyclitis and iridochorioiditis and not cases of acute attacks with many recurrences, but only the cases that begin without or almost without evidence of external inflammation and so run on for years and only perhaps in the late stages, if at all, are associated with marked external inflammation. The patient notices his disease first by disturbance of vision. Objectively these cases are marked by deposits on the cornea, posterior synechiae, opacities of the vitreous and often by changes in the chorioid. It is conceivable that agencies noxious to the uveal tract may attack now one part and now another and an inflammation of the chorioid may slowly involve the iris and vice versa. If we wish to use a more definite name than uveitis we must decide on what clinical grounds we may make such a distinction. With visible changes in the iris tissue or posterior synechiae we are justified in speaking of iritis; with foci in the chorioid, of chorioiditis. In the numerous cases with no visible change in the iris, but with precipitates on the cornea and perhaps opacities in the vitreous, called serous iritis, the name iritis does not seem clinically justified. Despite the close connection of iris and ciliary body, involvement of one without the other may occur. The author has four cases, anatomically investigated, in which the ciliary body remained free during long continued inflammation of the iris and these were by no means light cases of iritis, one having seclusio pupillae. The question whether cyclitis occurs without iritis is not to be answered exactly, though with dense precipitates on the cornea the iris may show a very slight infiltration anatomically and none clinically. In the author's opinion chronic cases of unmixed cyclitis occur in the cases of heterochromia of the iris with precipitates in the lighter colored eye. These cases do show a peculiar atrophy of the iris tissue. The signs in the iris may be almost negligible with a very marked cyclitis, so Fuchs speaks clinically of chronic cyclitis in these cases with precipitates on the cornea and without perceptible changes in the iris. Precipitates are a frequent but not indispensable sign of chronic uveitis; they may be present at times and then absent in the course of a disease extending over years. They merely show the lymphocytic nature of the exudate and therefore the chronic course of the inflammation. The fresh inflammatory changes consist in cellular infiltration of the uvea with immigration of cells into the aqueous and into the anterior part of the vitreous. The older changes are proliferation of tissue, especially of the ciliary epithelium, adhesion of structures to each other and organization of membraneous exudates. The cells found in the aqueous and in the tissue of the uvea are mostly lymphocytes, as is the rule in chronic inflammatory processes. The kind of cells found in the exudate depends on the intensity of the inflammation and not on the nature of the exciting cause. Many of these lymphocytes later undergo a change, their nuclei become larger, longer and lose some chromatin, and the protoplasmic body larger. These large lymphocytes are relatively scarce in the tissues but form the majority in the anterior chamber exudate. In the tissue we meet also scattered polynuclear leucocytes, mast cells, eosinophiles

and plasma cells; the mast cells frequent, the eosinophiles rare. Occasionally plasma cells are found almost exclusively. The characteristic exudate is the precipitate on the cornea; anatomically this occurs in two forms which may be called pseudo-precipitates and true precipitates. In cases of the pseudo precipitate a continuous cell layer which is of unequal thickness covers the posterior surface of the cornea. In places there are gaps, in other places it is heaped up. The endothelium is frequently altered under the deposit. The pseudo-precipitate occurs most often in mild traumatic iritis. True precipitates occur in endogenous iritis. Of course exceptions are found. The true precipitates are fairly compact, well defined clusters of cells sometimes almost spherical, like little hills with steep sides, or flat on top and with a surface irregular from projection of cells. Between the separate precipitates Descemet's membrane is either entirely clear or here and there spotted with single cells or with a few grouped together. Under the true precipitates the endothelium is normal, perhaps under large and old precipitates there may be a gap. In the case of pseudo-precipitates the leucocytes in the aqueous singly become attached to the cornea; in true precipitates leucocytes free in the aqueous unite into balls and then, as a mass, become attached to the cornea. A further growth of these is not excluded or neighboring ones may coalesce. True precipitates mark spontaneous chronic iritis, pseudo-precipitates mark the more acute cases, especially those of traumatic origin. Clinically, strong magnification may show the pseudo-precipitates as small dots, not regularly round and not sharply outlined, and white or gray. True precipitates are small, but sometimes larger, fairly round, sharply outlined, often yellowish or brownish. They may remain months while the pseudo-precipitates are of short duration. Both kinds of precipitates are composed chiefly of lymphocytes which are larger than those forming the exudate in the iris. In precipitates of short duration the cells are clear, well stained, and granular, while in older ones the cells run together, stain poorly and are little, or not at all, granular. Occasionally isolated polynuclear cells are found and often fibrin. Pigment granules are common like the chromatophores of the uvea, sometimes in large spheres giving a black or brown color to the precipitates. The precipitates are distributed by centrifugal force over a triangular area, or chance may govern their arrangement or their situation may correspond to an inflammatory focus in the cornea. Resolution of the precipitates begins at the base and they disappear in most cases without leaving a trace or they may become darker with time and remain permanently. Rarely the precipitate organizes to connective tissue. The question of the origin of the leucocytes which form the precipitates is yet undecided, some authors favor origin from the iris, others from the iris and anterior part of the ciliary body together. Both these regions and the posterior part of the ciliary body as well can give rise to precipitates. Deposits occur on the iris and on the lens capsule in the pupillary space and may be seen on the tissue of the iris, when they are large enough. Fuchs thinks the old view right that precipitates on the iris and in the pupil occur when the patient lies on his back, as during sleep. True precipitates do occur on the retina.

From a clinical standpoint we may distinguish three groups of endogenous chronic uveitis: (1) Light cases with precipitates without posterior synechiae; a chronic cyclitis lasting years without much change. The first serious complication aside from opacities in the vitreous may be increase of tension. In this group may be placed the cases occurring in heterochromia iridis. (2) Cases of medium intensity with posterior synechiae as well as precipitates. In time seclusio pupillae may result. (3) Severe cases ending in atrophy of the eyeball. Of course these groups grade into each other. Now anatomically we may make five groups: (1) Cases with changes in the iris (and often in the chorioid) without involvement of the ciliary body. In the iris, light infiltration and later atrophy of the tissue, adhesions of the pupillary edge to the capsule and a membrane in the pupil only or also on the anterior surface of the iris. (2) Cases with changes in the iris and also in the ciliary body. (3) Cases with membranes in the interior of the eye on the ciliary body and often also on the chorioid. Total separation of the retina and atrophy of the eyeball often follows. (4) Cases with changes resembling those of sympathetic ophthalmia. (5) Cases with great infiltration of the uvea and also of the retina with necrosis of this organ. As to etiology, groups 1 and 2 may be attributed to a slight but continuous irritation working on the surface, probably from the presence of an irritating agent in the aqueous. Group 3 has organized membranes which are like those in exogenous uveitis after perforation. Some of our cases may have such an origin, though hardly the bilateral ones. Some may be of metastatic origin. Group 4 and 5 suggest a parasite in the tissues perhaps coming from the blood. The iridocyclitis after separation of the retina is of endogenous type and not caused by microorganisms but may be ascribed to the irritative agency of the subretinal fluid. Fuchs had 15 such eyes to study. An early case showed very slight infiltration of iris and ciliary body with lymphocytes and an adhesion of pupillary edge to anterior capsule. The older cases showed in one half of them, seclusio pupillae and pushing forward of the iris, and the half without iris bombé showed either (1) incomplete adhesion of pupillary edge to capsule or (2) a complete fusion of surface of iris to the capsule or (3) subluxation of lens or (4) increased tension. If the separation of the retina is not primary but secondary to an endophthalmitis there are characteristic membranes at the ciliary body and surface adhesion

of iris to lens and so no iris bombé. The inflammation often limits itself to the pupillary edge forming an annular synechia while on the posterior surface of the iris and the ciliary body there is no exudate. A membrane forms in the pupil and may extend on the anterior surface and also a little posteriorly on the capsule so as to take the pupillary edge between its two layers. New vessels may form in the anterior layer and if the pupillary edge is not entirely bound down, contraction may cause an ectropion of the pigment layer and sphincter. The stroma of the iris may be free from infiltration and show an atrophy of various grades or slight infiltration may occur like that in chronic uveitis. Two thirds of the cases show changes in the ciliary body either a light diffuse infiltration throughout or the pars plana alone may show the severer types. The chorioid even back to the papilla may be involved and very large "Drusen" of the lamina vitrea are found.

HYPOPHYSIS DISEASE.

Emory Hill's[11] paper should be read in full. His third section on the eye symptoms of hypophysis disease is abstracted as follows. Enlargement of the hypophysis, from its position, may produce a great variety of eye symptoms. Exophthalmos and other pressure effects are frequently absent and their presence does not aid in distinguishing between the acromegalic cases and those representing a hypofunctioning gland. Palsies of ocular muscles in fact are more frequent in the latter type. Authors give temporal hemianopsia in from 38% to 46% indicating that temporal hemianopsia is not essential to the diagnosis and we may recognize the disease long before this symptom is present. Cushing says: "The primary defect usually involves the color boundaries alone in one upper temporal quadrant and the temporal field is gradually involved. The color fields are involved first and the form fields later. The macula region, spared for a long time, is implicated first in its temporal half and then wholly. Rarely are the two eyes affected in an equal degree. Homonymous hemianopsia occurs in a number of cases. A great variety of contractions of the visual fields may be found. Color interlacing and daily variations in the fields are found frequently." Amblyopia and amaurosis are late findings. Primary optic atrophy is more frequent than neuritis and secondary atrophy. When intracranial pressure is a late and rapid development choked disc may be imposed upon a primary atrophy. Scotomata, contrary to the older view, are frequent and important and may represent the beginning of larger defects which will become hemianopsias.

BLUE SCLEROTICS AND FRAGILITAS OSSIUM.

Within the last three years the inherited nature of this congenital peculiarity has been proved. The patients have the sclera of a bluish tinge described by Stephenson as leaden and by others as pale azure blue usually uniform in color from cornea back to equator, though the ciliary region may be deeper in tint. Von Ammon first described it in 1841 and in 1903 Buchanan examined a case anatomically finding the sclerotic one third of its normal thickness. Peters[12] in 1908 first mentioned its hereditary transmission. The patient, his father, his uncle, one cousin, an aunt and a grand parent were said or known to have had blue eyes of this sort. Four generations were affected. Four of these cases had a typical embryontoxon, which may accompany many congenital misformations. Abnormal transparency or abnormal thinness of the sclera may account for these cases and Peters inclines to the latter view. There was no sign of stretching, either buphthalmos or even myopia in his cases. Stephenson[13] in 1910 reported a case with a small embryontoxon towards the upper margin of each cornea and a congenital crescent at the lower margin of each optic disc. He found 32 individuals in four generations and 21 had eyes similar in appearance to the patient, 7 were males and 14 females. Harmon[14]further investigated this family, covering 55 individuals and 5 generations, of whom 30 had this congenital peculiarity. The hair varied from dark to yellow and the irides varied equally. Most of them had astigmatism of considerable amount and Fuchs coloboma of the lower edge of the disc. Harmon ascribed the defect to unusual thinness of the sclera. There were 12 males and 18 females. Inheritance was through females always. Eddowes was apparently the first to note that persons with blue sclerotics had frequent fractures of the bones. He thought the condition of the sclera indicated a want of quantity or quality in the fibrous tissue of the body. Burrows in 13 cases of blue sclerotics found 9 who suffered from fractures from trivial violence, and of 16 persons in the same family with normal sclera none had had fractures. Adair Dighton[15] in 1912 reported 9 cases in four generations and five of them were victims of fractures often repeated from trivial causes. Peters[16] again in 1913 reinvestigating his family found the father and two sons had had seven fractures of the long bones. Conlon[17] reports a family where the blue sclerotics appeared in five generations. He saw personally a father and five children all affected and all with embryontoxon, and three children had a liability to fracture from slight violence, while the history showed fractures common in the family. No one of the six seen had Fuchs coloboma. Conlon believes the explanation of the color is abnormal transparency and not abnormal thinness of the sclera and that the case examined histologically by Buchanan was not a typical one. Conlon had x-rays of fibula and tibula taken showing both bones with a much enlarged medullary canal and a thin cortex. The shaft of the fibula was enlarged irregularly

and the cortex was almost entirely wanting at the enlarged places. The wrist bones showed a similar condition. All the bones showed atrophy and a lack of density.

Reports of Societies.

THE AMERICAN NEUROLOGICAL ASSOCIATION.

THIRTY-NINTH ANNUAL MEETING, HELD AT WASHINGTON, D.C.

MAY 5—7, 1913.

THE PRESIDENT, DR. PEARCE BAILEY, NEW YORK, IN THE CHAIR.

(*Concluded from page 62.*)

THE RÔLE WHICH HEREDITY PLAYS IN INDUCING EPILEPSY IN CHILDREN SUFFERING FROM INFANTILE PALSY.

DR. L. PIERCE CLARK, New York, and DR. EDWARD A. SHARP, Buffalo, N. Y.: In a comparative analysis of some 886 cases of epilepsy, divided equally between those suffering from the idiopathic disease and hemiplegic epilepsy, we found that the heredity charts of the two classes were practically identical quantitatively and qualitatively. We, therefore, deduced the conclusions that the prognosis in any cerebral hemiplegic child predisposed to epilepsy because of his palsy was enormously increased by the presence of a hereditary neuropathic constitution in a given case, and that the palsy *per se* played a secondary rôle and a much less important one than heretofore supposed.

DR. E. E. SOUTHARD, Boston: At the Psychopathic Hospital, the chief of the out-patient department, Dr. Lucas, has been working upon heredity in epilepsy, and an interesting confirmation of Dr. Clark's conclusions are in process of being obtained. Our investigator has spent some eight months upon the heredity in these cases, and had unfortunately been unable to establish what the speaker and his associates thought she might establish, namely, the difference in the heredity features in the organic and inorganic cases. I would judge that an intensive work upon this small number of cases would entirely confirm Dr. Clark's results.

THE FEEBLE-MINDED IN MASSACHUSETTS OUTSIDE OF INSTITUTIONS.

DR. WILLIAM NOYES, Boston: This inquiry was undertaken under the direction of the State Board of Insanity, which has the duty of recommending to the Legislature the provision that should be made each year for the institutional care of the feeble-minded. Heretofore no data have existed that would give an adequate idea of the extent of the provision needed because of the varying estimates of the number requiring institutional care. All the available sources of information were utilized, and the data received were entered on cards, one for each individual. The cards, finally brought together in alphabetical order to prevent duplication, showed a listing of 5,007 individuals, 2,640 males and 2,367 females, who were considered by one or more persons as being feeble-minded. These totals do not include returns from the schools of the five large cities of Boston, Cambridge, Lowell, Fall River and Salem. It is estimated that there are ot least 628 institution cases in the schools of Boston. It is easily seen, therefore, that the institution cases in the schools of the four other cities would increase the totals in a very marked degree. On the other hand, it must not be assumed that the 5,007 individuals listed in the census are by any means all institution cases. Defective delinquents have been rejected when known to be such. For the purpose of comparison with the state census of 1905 a more intensive study of a given section, including twenty-one towns, was made. One hundred and five feeble-minded individuals were found, while the state census gave but 37, a very marked difference. If the same proportion held throughout the state, the total number in the community would be 7,861. A committee has prepared tables estimating the cost to the state of three feeble-minded families,—the W family and two branches of the B family. The tables are made on the estimated cost of caring for a feeble-minded child by the State Board of Charity at $180 a year until the average age of thirty-three. The totals of these feeble-minded children are as follows: 9 members of the W family will cost the state $30,705; 7 members of the B-I family will cost the state $21,470; 3 members of the B-II family will cost the state $12,600.

DISCUSSION.

DR. L. PIERCE CLARK, New York: I consider the census which Dr. Noyes has made highly important from many points of view. I am rather surprised to find from Dr. Noyes that the number of feeble-minded in Massachusetts is relatively small. In New York City alone there are over 7,000 uncared-for in the schools, even at a conservative estimate, without a definite census being made. In New York, the profession had doubts as to whether the special classes for instruction could serve other than as a makeshift until segregation in colonies could be undertaken. It was the best thing that offered itself.

DR. NOYES: Segregation with us means merely committing the subjects to the schools at Waverly and Wrentham, state institutions. Of 87 women under the charge of the state board of adult poor, 68 were known to have had children—92 illegitimate and 17 legitimate; making a total of 109 children born by 68 feeble-minded and borderline mothers. The statistics did not, as a rule, include the borderline cases because for various reasons authorities would not report a case unless pretty well marked. I believe that all states having to deal with this problem will have to come to this, that there shall be a definite census made of them

and of those the profession would look on as more dangerous, and that the state shall assume charge of all these and say they cannot have their liberty.

DR. DANA, New York: The latest estimate of New York state has something about 5,000 of this class; and so it seems to me the estimates mentioned by Dr. Noyes rather confirms the estimates made in New York.

DR. NOYES. I was surprised and gratified when the inquiry into these special towns came out that it practically agreed with what is generally put out, about 1 in 500. I obtained the information myself in the summer time, interviewing by telephone and verbally all the physicians and the superintendents and supervisors of the poor.

LESIONS OF THE HYPOPHYSIS FROM THE VIEWPOINT OF THE SURGEON.

DR. CHARLES H. FRAZIER, Philadelphia: I present the results of four cases of hypophyseal disease in which the hypophysis had been approached by his transfrontal intracranial method. There were no operative fatalities. I would call attention to the advantages of this over the transphenoidal method, as indicated by my own experience and from a review of 65 operations by various surgeons who have used the extracranial approach, and to the difficulty in determining before the operation what the nature or size of the lesion is. The same clinical picture is present in all sorts of hypophyseal lesions, including hyperplasia, benign and malignant growths. Any one of these lesions may lead to evidences of hypo- or hyperpituitarism or to neither. The only evidence of pituitary disorder in many cases is revealed in the visual disturbances and the signs of intracranial tension without the least suggestion of the perversion of the metabolic processes. Much confusion that has arisen in the minds of the experimentalist as to how vital the hypophysis is for the maintenance of life, and I am inclined to accept the opinion of those who have found in animals that complete removal is not incompatible with life. I would refer to the further confusion in the minds of the pathologists as to the classification of pituitary tumors, and show how comparatively benignant is the life history of certain malignant lesions, so that in the presence of malignancy the beneficial effects of operation would extend over a number of years. I review the indications for surgical therapy, the beneficial results of which are seen in the majority of instances in the relief of the visual disturbances, headache, psychic disorders, and to a less extent of the symptoms of acromegaly and dystrophy. I find it of advantage on my own cases to combine glandular feeding with surgical intervention, and I do not believe that operation should be resorted to, except in the presence of impending blindness, until glandular feeding has been given a trial. I am fully convinced that in the future the transfrontal method of approach would be adopted by the general surgeon, and, if the transphenoidal method is used at all, it should be practised only by the specialist trained in the technic of intranasal procedures. Palliative procedures, such as temporal or sella decompression are only of questionable value and only transitory in their influence upon the symptoms.

DISCUSSION.

DR. CRAMER: In 1911 there was brought to me a patient who, in 1873, had become completely blind. This, of course, was before the days of pituitary agitation or much pituitary knowledge. In 1911 she appeared with the pituitary syndrome and died with inanition in the latter part of that year. Here was a patient who lived with pituitary tumor, blind, from 1873 until 1911. If operation cannot influence or retard the development of compression symptoms, it makes no difference how safe the operation may be, whereas, if the intracranial route will do this to a greater extent because, as I have pointed out, the tumor most frequently grows upward, that operation is the one that should be developed.

DR. ALFRED REGINALD ALLEN, Philadelphia: In the past year Dr. Frazier has sent me four specimens of scrapings or excisions from a part of the pituitary. The point of interest is the discrepancy of opinion of various men as to what these growths are. I have been greatly interested in the peculiarity of the process simply from a morphological standpoint, and whereas, the profession has a very complete idea, from the histological and histopathological aspect, of chronic interstitial nephritis and many other things of that kind, yet when we come to the pituitary our knowledge is very slight. I believe that one reason for knowing so little is that the surgeon digs out a piece in the operating room and sets it aside, and the piece remains until after the operation, and in the meantime dries out and reaches the pathologist's hands in bad condition for study. If surgeons would care better for these tissues we would soon know a great deal more about the histo-pathology of neoplasms of the pituitary body.

DR. HERMAN HOPPE, Cincinnati: I have in my possession a brain tumor that was obtained before the days of the x-ray, and also before the days of much knowledge of hypophyses. It is a hard fibroma that is probably two inches in diameter. It never could have been removed by the transnasal route. Today this case would be diagnosed at once, and that tumor could have been removed very easily by the transfrontal route. This man's life would have been saved, absolutely, providing the surgical technic had been successful.

DR. CHARLES H. FRAZIER, Philadelphia: In my paper I tried merely to state the problem from the standpoint of the pathological features with which surgeons had to deal in order to open the way to some conclusion as to the best method of dealing with this problem. I tried to be conservative, at least in my estimate of the usefulness and the limitations of surgery. The point I wished to emphasize, however, was that these so-called malignant lesions do run a very benign course, and when these tumors are large in proportion, they grow up towards the hemispheres, not down, so that they were more readily approached from above, also that in most of the operations done through the endonasal methods, there had been a very incomplete removal of what in many instances was a very large tumor, and, lastly, that, in the hands of most surgeons discussing general surgical procedure, the intracranial method would prove to be the safer of the two. When one recalls to mind the anatomical feature of these two operations, it will be observed that one can draw a line from the tip of the nose, or one appproximately from the upper lip back through the spenoid process to the sella turcica, which line would be longer than a similar line through the supraorbital ridge to the sella turcica. If, in the early stages of the operation, one punctures the dura over the frontal lobe, so that during

the subsequent stages the cerebrospinal fluid is allowed to escape as freely as it may in order to afford an opportunity for the displacement of the hemispheres from that portion; if one displaces the frontal lobe upwards, with the patient's head in the so-called Rose position; if then, one has a suitable headlight, which in some instances is necessary and in some not, according to the character of the day, a very correct view can be had down to the optic foramen, or down to the point where the optic nerve passed through the optic foramen. It is not necessary to remove the rim of the foramen. When you are at the apex of the orbit you are really within a trifling distance of the pituitary body; and it remains then only to make a transverse or horizontal incision in the dura about a quarter of an inch above the floor of the base of the skull in order to avoid the sinus, it remains only to make this horizontal incision in the dura to expose the contents of the sella turcica. As thus described, this sounds like a very simple procedure, which it is. In most instances it is simpler than the exposure and removal of the Gasserian ganglion; this is not because I am partial to the operation, but I think there are other surgeons who have tried the method who will confirm what I have said. I had a conversation last night with Dr. Elsberg of New York, who has done the operation only once, and he had been really surprised at the comparative simplicity of it and at the facility with which he reached the sella turcica and exposed a large round growth, and subsequently removed it with most striking results. The matter is still subject to question and we cannot come to any definite conclusion on one side or the other, but I still feel that eventually we will find that, if the pituitary body be approached, and, if the lesions of the pituitary prove to be amenable to surgical therapy, the transfrontal approach will be the more desirable of the two.

OFFICERS FOR 1913-1914.

Dr. Henry Hun, Albany, President.
Dr. Alfred Reginald Allen, Philadelphia, Secretary-Treasurer.

NEW ENGLAND PEDIATRIC SOCIETY.

A combined meeting of the Pediatric Section of the New York Academy of Medicine, the New York State Society, the New Jersey Pediatric Society, the Philadelphia Pediatric Society and the New England Pediatric Society was held in Boston, November 8, 1913. The morning was spent in visiting the various hospitals. Dinner was served at the University Club at 6.30 P.M. At 8.15 P.M. the combined societies met in John Ware Hall, Boston Medical Library. The following papers were read, and discussed:

1. On the Bacteriological Diagnosis and Treatment of Alimentary Disease in the Infant and Child, by Dr. Ralph Vincent, London.
2. Investigations in Vulvovaginitis by means of the Female Urethroscope, by Dr. John F. Sinclair, Philadelphia.
3. Active Immunisation in Diphtheria by Toxin-antitoxin, by Dr. William H. Park, New York.
4. The Position of the Stomach in Children, by Dr. James Warren Sever, Boston.

JAMES S. STONE, M.D., CHAIRMAN.
FRITZ B. TALBOT, M.D., SECRETARY.

DR. RALPH VINCENT of London, England read a paper

ON THE BACTERIOLOGICAL DIAGNOSIS AND TREATMENT OF ALIMENTARY DISEASE IN THE INFANT AND CHILD,

and demonstrated it by lantern slides.

Abstract: The organs are grouped according to the conditions determining their growth in their action upon milk. (1) Bacteria producing lactic acid but not producing gas. (2) Bacteria producing lactic acid, carbon dioxide and alcohol. (3) Bacteria growing in "pasteurized" milk. (4) Bacteria growing in milk after it has been raised to 100° C. The colon organisms were capable of acting proteolytically in certain conditions and when these conditions were present alimentary toxaemia was established. He had recently devised a method of differential staining by means of which the colon organisms could be recognized by direct microscopical examination of the stained film, and this had proved to be of great value in regard to clinical diagnosis.

DISCUSSION.

DR. C. H. DUNN: I have always been particularly interested in the bacteriological side of these diarrheal conditions. I think that Dr. Vincent's paper touches the main point at issue in the present stage of advance in our knowledge of the gastroenteric disorders. There have been two groups of men working upon this condition, one group entirely along chemical lines, and they come out with the results of fat intolerance, carbohydrate intolerance, proteid intolerance and so forth, and I think that this group has been rather too much inclined to neglect the role of these bacteria. On the other hand, the other group of men have been working along bacteriologic lines and they have been very much inclined to neglect the chemical aspects. I think what we need now is to bring the two separate lines on which the investigations have been carried out into closer harmony. I have always been convinced that an important part was played by the conditions of over acid fermentation on the one hand and putrefaction of the proteids on the other in a great many of these cases. It seems as if as the result of the work of Kendall and others we had gotten to the point where we were all ready for our treatment and had an idea of what bacteriologic processes were going on in the intestine if only we could recognize them clinically. We were ready to treat them with the proper diet or by introducing the proper organism, and we have known that in some conditions a great many cases can be very effectively treated by introducing acid-producing organisms, but what we have lacked most is some laboratory method for distinguishing one type from the other. Heretofore we have not been able to tell which organism was present and therefore we have not been able to tell which treatment was best to apply. If this work of Dr. Vincent is going to give us a rapid and systematic laboratory method of telling us whether we have to do with colon infection, conditions of putrefaction or overgrowth of the acid organisms, I think it will be exactly what we have been waiting for and what we need.

DR. JOHN F. SINCLAIR, Philadelphia, read a paper on

INVESTIGATIONS IN VULVOVAGINITIS BY MEANS OF THE FEMALE URETHROSCOPE.

Abstract: The purpose of the paper was to suggest improved methods of prophylaxis.—The study was based on 83 cases admitted to the Babies' Hospital of Philadelphia, which has been endoscopically examined. All were under three years of age. Both vulvar and vaginal smears were taken and examined bacteriologically. Careful notes were made of the conditions of the cervix and vaginal mucosa upon endoscopic examination.—The complement fixation test was employed in ten cases and was positive in fifty per cent. Of the 83 cases examined 16, or 19%, were found to be infected with the gonococcus, at the time of admission to the hospital, or to present highly suspicious evidences of such infection. Seven cases, negative upon admission subsequently developed vaginitis of specific origin. The early recognition of the infectious agent in latent cases is of immense importance in instituting proper prophylactic measures. Over twenty-one per cent. of the total number of cases examined would have escaped detection without the use of the endoscope. Only 30% of the babies in the "positive" and "suspicious" groups showed any visible signs of a discharge upon admission.

He concludes that to be effective prophylaxis must begin with a campaign of education in the homes where infants are born and raised, as well as in all manner of institutions which have to do with the various phases of child welfare. Day nurseries, infant and orphan asylums, hospitals, shelters, public bath houses, recreation centers and even our school houses are prolific sources of infection, and will continue to be, until adequate medical supervision is exercised and individual cases are isolated until free from the specific organism.

In day nurseries, shelters, foster homes of every description, and in hospitals, every child should be carefully examined upon admission for clinical and bacteriological evidences of gonococcal infection and promptly removed or isolated if the findings are positive. Proper isolation in institutions demands employment of special nurses, who shall have no other duties, or in any way come in contact with babies or children in other departments of the institution. The lay helpers should be free from gonorrheal infection and this should be determined by bacteriological examinations and by the complement fixation test. Systematic examinations of all inmates of such institutions should be made with thoroughness at convenient intervals that latent cases may be early detected and isolated before becoming new centers of infection.

In the case of public bath houses, recreation centers, and schools, efficient supervision should be exercised by properly qualified trained nurses so that every suspicious case may be promptly excluded and referred to a physician for treatment.

Boards of health should be empowered by law to make gonorrheal infections reportable and to exercise their authority along lines similar to those which they now employ in dealing with tuberculosis.

Medical attendants, especially gynecologists, and genito-urinary surgeons, should inform their patients clearly as to the nature of the disease and the danger of communicating it to innocent babes and children, at the same time giving minute instructions how they may safe-guard those about them.

Special clinics for the treatment of gonorrheal vulvovaginitis should be established in all the large cities as has already been done in Boston and New York.

DISCUSSION.

DR. RICHARD M. SMITH: Regarding the cases of which Dr. Sinclair speaks, it seems to me that one point of very great importance is the value of the complement fixation test. We have been in the habit of not considering a case, one of gonorrheal vaginitis, until we have had a positive smear, positive culture and positive fixation test. Some children have been kept from institutions or from school because of a vaginal discharge which on investigation proved to be not gonorrheal. It is very much worth while to be sure of the diagnosis. It also seems to me that a fixation test ought to be made in every case before it is called cured.

DR. WILLIAM H. BECK, New York, read a paper on

ACTIVE IMMUNIZATION IN DIPHTHERIA BY TOXIN-ANTITOXIN.

Abstract: Active immunization in 50 children has been carried out. Two mixtures were employed of toxin and antitoxin. In one, 66% of the amount of toxin required to neutralize 1 unit of antitoxin was used, in the other 50%. The children receiving the 50% addition of toxin produced very little antitoxin. Those receiving 66% produced in four fifths of the cases antitoxin varying from 1 to 6 units per cubic centimeter. The greatest amount was present at about the 10th or 12th day after the injection. The injections were given either as a single dose or divided in two doses at a week's interval. Absolutely no symptoms except in a few a slight local tenderness and a possible rise of temperature occurred. One fifth of the children developed no antitoxin and two of these developed diphtheria. This is a matter of great importance because not only does active immunization require several days to be established, but it fails in a certain percentage of the individuals. Immunization in hospitals or in institutions in which an epidemic of disease has occurred will probably be better treated by passive immunization with antitoxin. In the places in which on account of carriers the population is constantly apt to be infected, active immunization may be of value, much the same way as typhoid immunization is now practiced, except that in the cases of diphtheria it is to be applied to infants and young children rather than adults. Horses injected with these mixtures showed immunization on the third day and the greatest amount on about the seventh day.

DISCUSSION.

DR. EDWIN H. PLACE: It has been with great interest that I have heard Dr. Park's excellent paper, especially as the use of toxin-antitoxin mixtures were first suggested by Professor Theobald Smith. There has been, however, so much fear of unfavorable effects that no one has used them here—unquestionably an unfounded fear. It has been apparent to all working with diphtheria that great as has been the reduction of mortality, the morbidity has shown no clear or continued diminution since antitoxin came into use. The Boston curve as well as the New York figures fail to show that any real control over the prevalence of the disease has been secured and we are still dependent largely on

isolation. With the difficulty of recognition of the carriers at large and with the absence of any curative treatment for carriers, isolation has not gone to the desired extent as a preventative. These efforts to secure active immunization are therefore of much interest and importance. Dr. Meader last summer has studied at the South Department the effect of bacterial vaccines. But although there was a definite and usually marked increase in the bactericidal substance in the blood following vaccine administration, the disappearance of the diphtheria bacilli had no definite relation to this increase. It is unfortunate that more successful results were not obtained with the toxin-antitoxin mixture but there is hope that the future may know through these studies some great improvement in the control of diphtheria.

DR. WILLIAM H. PARK: I think as Dr. Place has mentioned, that possibly with the use of the bacterial protoplasm in addition to the toxin we may obtain not only antitoxin immunity but also bactericidal. Although it is somewhat discouraging to find that one-quarter of those injected are not immunized, yet three-quarters is really a pretty large proportion, and that possibly this will be increased with the use and development of the bactericidal immunization. It is at least sufficiently encouraging to attempt a further investigation. It seems absolutely safe I hope in connection with a number of colleagues to test the value of active immunization in a great many cases.

DR. JAMES WARREN SEVER read a paper on

THE POSITION OF THE STOMACH IN CHILDREN.

Abstract: The data from which the conclusions have been drawn in this paper have been gathered from a careful study of over eighty children. X-ray pictures were made of the children's stomachs in the erect position. In practically all instances the lower border of the stomach was found at or below the iliac crests. The shape of the stomach was usually of the sink drain type. The so-called ideal "cow's horn" stomach was rare. The organs were as a rule rather large. All were lower than what heretofore has been supposed to be the normal position, namely, the second lumbar vertebra. It was the inevitable conclusion from a study of these cases that a low stomach is not abnormal, but is probably where it belongs, and that there is rarely a pathological ptosis.

DISCUSSION.

DR. MAYNARD LADD: Almost all of my own investigations have been in infants under nine months of age, and have been done more with reference to determining the gastric motility than the position of the stomach, but I am certain that in the infants, at least up to that age, the stomach is a great deal higher than in the older children that Dr. Sever speaks of. The stomach is high in the young child. I do not recall now in my particular series any stomach the lower border of which reached down to the crests of the ilia, or anywhere near to that level.

DR. JACOBI: The position and shape of the stomach of the baby under nine months changes very rapidly from the vertical; at the end of one month it begins to be oblique, and at that time we frequently find it in front of the tenth dorsal. A careful observer has to take this into consideration also. In the very young baby the position of the stomach changes very often according to the food which it takes. Babies who are breast-fed have a different stomach from those who are artificially fed, and in artificially-fed babies the stomach will sink down even before this time. I think the lecturer will add to his data if he will take up the stomach of very small babies for the next year or two. The first demonstrations of the localization of the stomach are quite old, I have had to refer to it some time ago, and looked up some literature. The first paper I found on it was in *Unfeland's Journal* of 1825. There is a picture which shows the vertical position of the stomach at birth and very soon after. At the age of one month it begins to be oblique, and in a very few months more it changes considerably. I shall come again in a year or two and will listen to the reader's additional data.

DR. ARTHUR H. KIMPTON: I have had occasion recently to do autopsies on two very young children, one of three weeks, and one of four days old. The first one was a child normally born and gained weight at the rate of eight ounces a week for the first two weeks, but the first day of the third week it began to vomit and then vomited either five minutes or half an hour after taking food, not always immediately after. It was an undoubted case of pyloric stenosis. I saw the baby late in the evening and made arrangements to operate the next day as there was a palpable tumor, and the case was definitely one of pyloric stenosis, apparently not spasmodic. That child suddenly died before operation and at autopsy the stomach was in an oblique position high in the abdomen, higher than the text books tell us, and the photograph which I have to show you is practically the size of that baby's stomach as it came out. You will see the pyloric tumor, which is colored, and it is rather interesting to me because I had never seen a picture of a true pyloric stenosis. Dr. Whitney has the stomach as a specimen. Dr. Whitney said that the tumor looked to him like new growth than hyperplasia.

The other case was that of an infant four days old that began to vomit on second day, and was supposed to have had an artificial anus. You could pass your finger high into the rectum and palpate it with the other finger bi-manually. There was no pyloric stenosis. I saw the child after it had been vomiting for some time, and there was nothing to do but make an artificial anus. There was no large intestine to be found to make an artificial anus with, so I made one from the lowest loop I could get and made no attempt to find out where the obstruction was. The child died and an autopsy was done and the intestine examined from beginning to end, and that stomach, too, was extremely high, in an oblique position. That baby had to all intents and purposes no large intestine. It was about as large as a very small pencil and nothing in it, except putty-like material. The cause of the obstruction was about one inch from the ileo-cecal valve, due to bands coming up from the side of the pelvis catching it in a half-hitch and twisting it so that you had a mechanical obstruction. No meconium had ever gone into that large intestine. The baby passed marked quantities of this inspissated material, and it was white putty-like material, which came out in strings. We do not see enough of these cases to learn much from them. If I should see another case, I should look for an obstruction somewhere close to the cecum rather than high in the large intestine.

Book Reviews.

The Administrative Control of Smallpox. How to Prevent or Stop an Outbreak. By W. McC. WANKLYN, B.A. (Cantab.), M.R.C.S., L.R.C.P., D.P.H., Fellow of the society of Medical Officers of Health, and formerly referee in the diagnosis of smallpox and medical superintendent of the river ambulance service (smallpox) of the Metropolitan Asylums Board, London. 8vo., pp. 83. New York, Bombay and Calcutta: Longmans, Green and Company, 39 Paternoster Row, London. 1913.

Into this astonishingly brief book (hardly an hour's reading) Dr. Wanklyn compresses twenty-one years' experience in the handling and prevention of smallpox epidemics. The suggestions are concise, sound and practical, the illustrations interesting and illuminating. The book is aimed primarily at those who are or aspire to be public health officers, and the references are to British conditions, especially with regard to vaccination and to public health organization. The book will, however, find valuable application in any community which is only partly protected by vaccination and yet is constantly exposed to a dropping fire of infection from all parts of the world. Such communities are the rule in America as well as in England, a fact we are apt to forget, for where smallpox is not prevalent, nothing seems so remote. To our mind, the author places somewhat too much importance on the danger of importing smallpox "in clothes, rags and other raw material for manufacture," and draws an unwarranted distinction between the infectivity and the virulence of smallpox strains. The book affords valuable sidelights on the importance of vaccination, and is eminently sane and usable by anybody anywhere.

Taschenbuch der Magen and Darmkrankheiten. By DR. WALTER WOLFF. Berlin and Vienna: Urban and Schwarzenberg. 1912.

Dr. Wolff has put into a little book of 160 pages the more common and useful diagnostic and therapeutic procedures that are carried out in the Augusta Hospital in Berlin. The book bears the official approval of Ewald in the form of an introduction. It is a simple, clear, well written book, especially designed for students and practitioners. The book is sound and sane throughout. The discussion of the section on gastric diseases is complete. The discussion of intestinal diseases occupies less than twenty pages and is superficial and cursory. As a small handbook on diseases of the stomach the book can be heartily recommended.

A Text-Book on Gonorrhea and Its Complications. By DR. GEORGES LUYS, late assistant to the Urological Clinique, Hospital Lariboisière, Paris; prizeman of the Faculté de Médecine, Paris. Translated and edited by ARTHUR FOERSTER, M.R.C.S., L.R.C.P. (Lond.), late resident medical officer, London Lock Hospital. With 200 illustrations and three colored plates. New York: William Wood and Company. 1913.

This book is what its name indicates. It is a real text-book, and it is the most satisfactory and up-to-date record of this disease, as it exists in man, woman and child, which we have seen. The book is complete without being ponderous, is well written, well printed on good paper, and is exceedingly well illustrated. When compared with the many trivial and inefficient books, so frequently met with in this country and presumably elsewhere it is most convincingly adequate and efficient, both in its scientific and in its more practical and clinical aspects. That it has been so ably translated into the English language is cause for congratulation.

Taschenbuch der Diagnostik und Therapie der Lungentuberculose. By H. GERHARTZ. Berlin, Wien.: Urban and Schwarzenberg.

This is a small light volume of some two hundred pages of a size that would easily slip into a pocket or handbag. It contains much information in condensed and tabular form which must be of great value to German and Continental practitioners; it is of little or no value to the English and American profession. There are 48 illustrations, many of which illustrate methods of percussion of so elementary a nature as to be unnecessary; there are some useful diagrams showing the localization of tuberculous processes in various lobes, etc., and some excellent colored plates showing tuberculin reactions and pathological specimens. There are a few x-ray plates of mediocre quality.

The book is divided into four large sections: (*a*) the proof of tuberculous infections, which considers diagnostic tuberculin reactions, etc.; (*b*) the recognition of tuberculosis, a long section on diagnosis of all stages in which far too much attention is paid to sputum examination, the x-ray, and the diagnosis of cavities, etc., and not enough to early diagnosis; (*c*) the treatment of tuberculosis, in which many pages are devoted to the formulae of various drugs and tables of prescriptions, and only a few pages to hygienic sanatorium treatment; (*d*) the prognosis of pulmonary tuberculosis.

As is not uncommon with many such pocket editions the author tries to cover far too large a field and loses sight of many important points in a mass of unessential details. The book has many good points, however, and should be of value to German physicians.

THE BOSTON
Medical and Surgical Journal

THURSDAY, JANUARY 15, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States. $6.50 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

TROPICAL MEDICINE IN ELIZABETHAN DAYS.

In the *Annals of Tropical Medicine and Parasitology* for May, 1912, Dr. Charles Singer, recorded some of his observations on "Early references to tropical diseases." Notably he referred to a remarkable book,* published at London in 1598 by one "G. W.," entitled "The Cures of the Diseased, in Remote Regions, Preventing Mortalitie, Incident in Forraine Attempts, of the English Nation."

In his dedication of this book to Queen Elizabeth, the author says:

"In my unjust imprisonment in Spayne, it pleased God to afflict me with a *Tabardilla* Pestilence; whereof being in cure by an especiall Phisition of the King, I observed his Methode for the same, and such other diseases as have perished Your Majesties people in the Southerne part. Which Remedies have since by my direction taken the like good effects."

"Tabardilla," Dr. Singer believes, may refer to yellow fever, dengue, or typhus. Other diseases described by "G. W." are "calenture," heatstroke or malaria, and "espinlas," of which he says:

"The partie having the Espinlas will be giddie in the head and have pain and pricking at his breast as with many thorns: wherefore I thinke it is so called of Spina and Espina, the Latine and Spanish words for a Thorne.

There will be upon the Huesso radio (*Anglice*, radial bone) or Focell, being the upper part of his armee, a hand breadth about the wrist, a little Kernell by which it is certainly knowne. And he that hath this Disease will not have appetite to meate and drinke."

This malady does not seem identifiable with any modern tropical disease.

Scorbutus is described under its Spanish name of "tiñoso":—

"It is an infecting Disease, Sufficientlie known unto Seafaring men; who by putrified meates and corrupted drinkes, eating Bisket flowrie, or foule crusted, wearing wet apparell . . .and slothful demeanour. . . obtained the same. The disease is so ordinary at Sea, as it hath seldome seen any Ship or Pinnice, to be foure moneths upon the Voyage. . . but some of the Companie have had this Disease. It is a certaine and assured medicine against this Disease to have such quantitie of Beere, brewed with Graynes and Long pepper, as in the morning twice everie weeke there may be given a good draught to a man. . . But White Wine or Syder, boyled and brewed with Graynes and Long peper, in like quantitie is very singular good. And it is not fit to suffer the gums to abound with flesh; and therefore sometimes let them bleede and cleere them withe strong Vinegar."

Apparently "G. W." was a navigator, perhaps a gentleman explorer, and not a physician, for in his preface he says:—

"The cause that induceth mee publiquelie to express the Cure of Diseases of such consequence (which) every judiciall conceite may perceive to have been the only prejudice to our Nation in the expeditions of our time to the Southerne parts; from whence they. . . have returned with renouned victorie, yet exceedinglie opprest withe extreame and penurious sicknesse, that hathe much more prevented the proceeding and performing of their pretensions than the power of Enemies, is not that a purpose, practitioner-like in Phisicke or Chirurgerie, to assume unto me anie knowledge in those Sciences and Faculties: But to possesse all men of remedies for such infirmities, as in my owne experience, have infinitelie impaired English Forces in intemperate Clymates, which I publish for the good of those whom cause may compell to have use thereof, and would be so censured of all."

With the recrudescence, in our own day and community, of the study of tropical disease, it seems particularly pertinent thus to turn back to this early treatise on tropical medicine from the Elizabethan days of Drake and Hakluyt and Frobisher and Raleigh.

* Reviewed in the *British Medical Journal*, November 23, 1912.

GERMAN MEDICAL INSURANCE.

In the issue of the Journal for Jan. 1 we commented on the conflict between the physicians and the insurance companies in Germany rela-

tive to the administration of the national medical insurance act. In view of this conflict, the Prussian government has now issued a new imperial insurance order, of which paragraphs 368 and 370 deal with the methods available to the insurance societies, should the latter fail to secure the services of a sufficient number of physicians to administer the act.

"Paragraph 370 authorizes the insurance societies to pay over a lump sum of money to the insured persons in lieu of medical attendance, medicines, and certain appliances, provided that the insurance societies can show that through no fault of their own they have been unable to secure the services of a sufficient number of medical men under contract. The offer of a contract on the part of the medical practitioners must contain 'suitable or appropriate' provisions (*angemessene*), and it is on the interpretation of this particular word that the action of the Prussian ministers is based.

"Paragraph 368 provides for the giving of medical treatment in the absence of any contracts at all. In this instance the doctors employed would be the so-called 'advisory staffs,' or medical men who, in defiance of the medical organizations are prepared to do work for the insurance societies, but will not put their names to paper."

The Prussian government has further determined that the word *angemessene* shall be so interpreted that if "the doctors offer service with free choice of doctor, the institution of arbitration courts, and the right of control by medical organizations, the society will be justified in regarding the provisions as unsuitable. This decision indicates that the government attitude is adverse to the physicians.

In the issue of the *Berliner Aerzte-Correspondenz* for Dec. 13, 1913, the executive of the federation of German medical societies, in conjunction with the Leipzig League, published a statement pointing out that the struggle is not directed against the beneficiaries, but only against the executives and managers of the insurance societies. This statement further contains a number of general and special instructions to local medical societies in dealing with conditions which may arise under the provision of the above paragraphs. It appears that the German physicians are determined to oppose the government and the insurance societies fearlessly in the maintenance of their rights, and it is to be hoped that their opposition may prove more efficacious than was the case with the medical profession of England.

TYPHOID IN THE ARMY AND NAVY.

REPORT from Washington, D. C., on Dec. 31 states that during the year 1913 the United States Army, with an enlisted strength of over 80,000, had only two cases of typhoid fever, neither fatal, one of them being in a man not immunized by antityphoid inoculation. Prior to 1910 there used to be about 250 cases, with 25 deaths annually. In 1910, the year voluntary inoculation was begun, the incidence rate was 2.32 per 1000. In 1911 it was 0.8; in 1912, 0.26. It is interesting to note that coincidently the incidence rate of tuberculosis has fallen from 4.7 per 1000 in 1909 to 3.49 in 1912.

Among the 40,000 sailors of the United States Navy there were only 7 cases of typhoid fever, with no fatalities, during the year ended June 30, 1913. The incidence rate of typhoid in the navy in 1911 was 3.61 per 1000; in 1912, 0.92; in the nine months ended Oct. 1, 1913, only 0.3. Antityphoid inoculation in the navy was begun later and has proved harder to enforce than in the army. Its benefit as a prophylactic procedure in both branches of the service seems established beyond question.

MARRIAGE AND EUGENICS IN WISCONSIN.

REPORT from Milwaukee, Wis., on Jan. 7 states that, in view of the difficulty of securing medical certificates under the new eugenic marriage law, persons intending matrimony are taking advantage of the common law marriage, which is legal upon filing a contract for a fee of ten cents. The Ashland Medical Society has voted to furnish examination certificates, including the Wassermann test, for a fee of eight dollars. One man who wished to marry a girl in order to legitimize his expected child by her, was refused license to do so because he had no certificate. Apart from its bearing on eugenics, this action seems at least somewhat unjust to the girl and the child.

MEDICAL NOTES.

DISCONTINUANCE OF SEX HYGIENE LECTURES.—Report from Chicago states that on Jan. 7 the local board of education voted to discontinue the

giving of so-called sex hygiene lectures in the public schools, after a trial of one year.

THE ANTIQUITY OF THE TRUSS.*—At the site of an old Franco-Roman village, just south of Clermont-en-Argonne, were found two trusses of iron, dating from the eighth century; one a left inguinal, so damaged and soiled that it was almost disintegrated; the other heavier and better preserved, a right scrotal, with a scrotal pad of about 5 cm. dimensions. Most of the relics found in the excavation of this town have been sent to the Museum Saint-Germain-en-Saye, where they are kept in a special cabinet, the gift of Dr. Mennier of Laroye.

OPERATION ON KING ALFONSO.—Report from London on Jan. 1 states that King Alfonso, of Spain, has recently come to London for the purpose of having a growth surgically removed from his throat.

A LONG RETAINED LITHOPEDION.—In the issue of the *Lancet* for Dec. 27, 1913, is reported from Toronto a case of a lithopedion retained in the abdomen for 42 years, and during four succeeding normal pregnancies, and finally removed by laparotomy. This is believed by the author to represent the world's record in this regard.

SMALLPOX AT GUANTANAMO.—Report from Washington, D. C., on Jan. 6 states that 34 new cases of smallpox, nine of virulent character, have developed at the Guantanamo naval station among sailors exposed during the recent outbreak aboard the United States battleship *Ohio*. The station has been quarantined and the *Ohio* is being fumigated.

BOSTON AND NEW ENGLAND.

BOYLSTON MEDICAL SOCIETY.—On Friday evening of last week, Jan. 9, an open meeting of the Boylston Medical Society was held at the Harvard Medical School, to which all undergraduates and members of the medical profession were cordially invited. An address was given by Dr. J. M. T. Finney, associate professor of surgery at Johns Hopkins University and president of the American College of Surgeons.

AESCULAPIAN CLUB MIDWINTER MEETING.—Invitations have been issued to the twelfth annual mid-winter meeting of the Aesculapian Club of Boston, to be held at the Harvard Club on Saturday evening of this week, Jan. 17. The speakers will be Mr. Abraham Flexner, of the general education board of the John D. Rockefeller Fund, on "Some Aspects of the European Regulation of Vice"; and Dr. Richard P. Strong, professor of tropical medicine in the Harvard Medical School, on "Tropical Medicine as it Interests Us in Our Larger Seaports."

TWO LIVING CENTENARIANS.—Mrs. Clarissa Collins, of New Haven, Conn., who is said to have been born on Jan. 1, 1814, celebrated recently her supposed centennial anniversary. Her health is excellent.

Joseph Byxbee, a retired sea-captain of Norwalk, Conn., is said to have been born in 1810.

A CENTENARIAN.—John Weeks, who died on Jan. 5 at Norwalk, Conn., is said to have been born in June, 1808, at Fordham, N. Y., He had been blind for a year preceding his death, but otherwise his health remained vigorous until early last December.

WORK OF BOSTON DISPENSARY.—The recently published 117th annual report of the Boston Dispensary records the work of that institution for the year ended Sept. 30, 1913. During this period, 113,000 patients, of whom 11,000 were babies and children, visited the various clinics; and over 8000 patients were treated at their own homes. In the hospital for children 323 patients were received. To maintain and continue the present service of the Dispensary to the community, the sum of $30,000 is required annually, and liberal subscriptions towards this amount are urgently requested.

CHILDREN'S HOSPITAL CONVALESCENT HOME.—At the annual meeting of the corporation of the Convalescent Home of the Children's Hospital of Boston, held in this city last week, the secretary's report showed that during the past year 826 patients were treated at the Home.

BOSTON VITAL STATISTICS IN 1913.—During the year 1913, 9378 marriages and 19,299 births were recorded in the city of Boston, both numbers being larger than in any previous year. The total number of resident deaths was about 10,300, corresponding to a corrected rate of 14.1 per 1000, as compared with 14.2 per 1000 in

* From *La Chronique Médicale*, August, 1913.

1912. The gross death-rate (11,890 persons) remains the same as last year, 16.17.

"The rate for typhoid fever will be about .82 per 10,000 population, against the low record of .79 in 1912. If deaths of non-residents be deducted, the corrected rate becomes .69, against .68 in 1912.

The rates for scarlet fever and diphtheria are both higher than in 1912.

Per 10,000 population, the death-rate from scarlet fever will be about 1.06, against 1.04 for the preceding five years, and the death-rate from diphtheria will be about 2.12, against 2.60 for the preceding five years.

The particularly bright spots in the year's record are the low rate from pulmonary tuberculosis—about 14.4, against the previous low record, 15.2, made in 1912—and the estimated infant mortality rate, 107 per 1000 births registered."

NEW YEAR'S GIFTS AND BEQUESTS.—Mr. David D. Stewart, of St. Albans, Me., has recently made New Year's gifts aggregating $230,000 to 12 colleges, hospitals and charitable institutions of Minnesota, 9 of them being in Minneapolis.

The will of the late Dr. J. F. Frisbie, who died on Dec. 17, 1913, in Newton, Mass., contained a bequest of $25,000 for the foundation of a Frisbie Memorial Hospital in Rochester, N.H., the testator's native home.

The will of the late Horace W. Wadleigh, of Cohasset, who died at Boston on Dec. 26, 1913, contains public legacies of over $120,000. Among these are bequests of $5000 each to the New England Peabody Home for Crippled Children, the Boston Home for Incurables, the Industrial School for Crippled and Deformed Children, and the Boston Floating Hospital, and $2000 each to the Children's Hospital, Boston, the Massachusetts Charitable Eye and Ear Infirmary, the Vincent Memorial Hospital, the New England Hospital for Women and Children, St. Luke's Home for Convalescents, St. Monica's Home for Colored Women and Children, Roxbury, and the International Hospital, Naples, Italy.

NEW YORK.

OYSTERS AND THE PUBLIC HEALTH.—In the latest issue of the *Monthly Bulletin* of the City Health Department the subject of "Oysters and the Public Health" is treated *in extenso*. In the precautions taken by the department to insure that oysters sold in the city shall be free from contamination careful investigation of the physical conditions prevailing at the points furnishing the oyster supply has for some time past been systematically conducted, and particular attention has been paid to the location of the so-called "floats" and "drinks" situated not only within the city limits, but also in the surrounding country. While an outbreak of typhoid fever at Northport, Long Island, in 1912, which was at first supposed to be due to contaminated oysters, was subsequently demonstrated to be due to infected milk, a typhoid outbreak the same year at Goshen, Orange County, was traced by Stiles to oysters infected by "drinking" at the mouth of a sewage-polluted creek emptying into Jamaica Bay. In New York City, however, it is believed that oysters probably play but a small part, if any, in the annual autumnal rise of typhoid, for the infections constituting this rise regularly occur in July and August, a time of the year when there is only a very small consumption of oysters. Still, the sale of oysters at retail is regulated by permits specifying certain strict requirements, and somewhat more than a year ago the board of health passed a resolution declaring that it shall be unlawful to float oysters and other shellfish in polluted waters in the city, and that none which have been floated or treated with polluted water, or which are shown by examination to be polluted, shall be brought into the city or held, kept, sold, or offered for sale at any place in it.

COLUMBIA UNIVERSITY.—At a meeting of the trustees of Columbia University, held Jan. 5, the resignation was accepted of Dr. Livingston Farrand, junior professor of anthropology, who has been elected president of the University of Colorado. Dr. Francis Carter Wood, director of cancer research, at the request of that department, was assigned to a seat in the faculty of pure science. At the meeting a gift of $2500 for surgical research, from an anonymous donor, was announced, and among the other donations during the month was one of $100 from Dr. Willy Meyer, for the "Deutsches Haus."

TYPHUS FEVER AMONG IMMIGRANTS.—During the recent voyage of the Italian steamship *Roma* from Marseilles to New York, a case of typhus fever occurred on board. The vessel touched first at Providence, R. I., and was detained there in quarantine for a short time. On

her arrival at New York on Jan. 7, 250 of the immigrants aboard, 30 of them with suspiciously high temperatures, were removed and placed under observation at Hoffman Island for 14 days. Four of these persons have since developed typhus. The vessel has been disinfected. Meantime, report from Providence states that four cases and one death of typhus fever have occurred in that city since the coming of the *Roma*.

A Lonely Centenarian.—Joseph Wormuth, who died recently at Shinopple, Delaware County, was said to have been born in 1809. He was an early pioneer settler along the Delaware River, and fought in the ranks throughout the Civil War. He subsequently engaged in farming and lumbering, and remained in active and vigorous health until three months ago. He was a widower and leaves no surviving children.

Infant Mortality in 1913.—Report from New York on Jan. 5 indicates that the infant mortality rate in that city in 1913 was the lowest on record.

"The infant death-rate for the year is 102 per thousand births, the lowest infant rate in the history of the city. Last year the rate was 105.3 per thousand births. This means a decrease in the death-rate of 3.3 per thousand births, or the saving of over three out of every thousand babies born as compared with last year. The total number of deaths under one year of age from all causes in the greater city last year was 13,779. In 1912 there were 14,289 such deaths, that is 510 fewer babies died in 1913 than in 1912. Estimating on the increased population for the year, the report says this means a saving of 1,069 infant lives. The general health report of the city for 1913 shows a reduction in the death-rate per thousand population for all ages from 14.11 to 13.76."

Harvey Lecture.—The sixth lecture in the current series before the Harvey Society will be given at the New York Academy of Medicine on Jan. 17, by Prof. Victor C. Vaughn of the University of Michigan, on "The Phenomena of Infection."

9. Barnes, L. E. *Eyestrain.*

1. Muhlberg records a few observations in a series of eight thousand specimens of urine from applicants for life insurance. Cylindroids (mucin threads) in excess were found in about 5% of the samples, and subsequent specimens from the same individuals often showed numerous casts and traces of albumin. In one case of nephritis now under his observation casts are usually very numerous, but at times are almost entirely replaced by typical cylindroids. [L. D. C.]

7. Bartholow, P. *The Etiology of Pellagra.*
8. Goltman, A. *The Treatment of Bronchopneumonia in Children.*

6. Magida has been testing the value of acromial breathing as a diagnostic sign in apical phthisis at the Post-Graduate Hospital, New York. In this disease auscultation at the acromion process increases and amplifies all the auscultatory signs which are ordinarily obtained over the apices, so that a slight lesion should be detected more easily by listening at this place. The writer found "acromial breathing" present in all of 28 cases in the first stage, in 8 out of 14 second stage cases, and in 2 out of 10 third stage cases. He is convinced that this method deserves a place in physical diagnosis. [L. D. C.]

8. LOWELL, H. *Burn of Eyes from Contents of Golf-Ball Core.*
9. *CABLES, H. A. *Quinin and Urea Hydrochlorid in the Treatment of Sciatica.*

1. Bloodgood believes that the future success in the control of cancer lies in education of both layman and physician. He strongly urges early operation or exploration in the precancerous stage.

4. Womer states that the staphylococcus spray in diphtheria causes no unpleasant symptoms, but does not appreciably lessen the period of quarantine. The preparation and distribution of the spray is a laborious procedure, especially if there are many cases. Apparently most carriers do not spread the disease after sixty days from the day the disease begins. Public health officials could work more effectively if they had some practical method of determining the virulence of diphtheria bacilli form in the throats of carriers.

9. Cables has treated eight cases of sciatica with deep, but not intraneural, injections of a 4% solution of quinin and urea hydrochlorid in normal salt solution given on successive days until relief has come. The largest number of injections was eight. He thinks this method worth further trial. [E. H. R.]

12. LARSON AND BELL. *A Study of the Lesions Produced by Bacillus Proteus.*

1. Meyer and Hardenbergh conclude that the "Abortin test," as recommended by the English Commission, is thoroughly unreliable. They have prepared a purified material for intravenous injection, which has yielded encouraging results. But even with this modified material a high percentage of healthy animals show a positive febrile reaction. A positive reaction, even in an infected animal, does not show the stage or acuteness of the disease process.

3. Methylene blue was found to penetrate the tubercle, stain the living tubercle bacillus, and in some cases kill the bacillus in vitro, and in others lessen its virulence. When added to the culture media, a relatively small percentage of the substance inhibited the growth of the human tubercle bacillus. The author was unable to influence the disease in guinea-pigs through the therapeutic use of methylene blue.

5. Arlsin has made a thorough study of the influence of certain drugs upon phagocytosis. He found that the following general rules were true, *i.e.* substances favoring oxidation promoted phagocytosis and increased the immune bodies. The reverse of this general rule was found true in most instances. Alcohol, chloroform, ether, chloral, morphin and potassium cyanid depress phagocytosis in vitro. Conversely, sodium iodoxybenzoate, strychnin and certain colloid metals stimulate phagocytosis. The middle zone is occupied by such drugs as caffein and the antipyretics, which influence neither oxidation nor phagocytosis. It was found also that those drugs which depressed phagocytosis in vitro had a similar action when studied in vivo. He considers it important to consider with care the effects of agents on the processes of immunity when they seem indicated in infectious diseases.

9. The bacterial flora of human feces is characterized in general by the presence of streptococci producing large amounts of acid in dextrose (3.5-4%). The most frequent in occurrence is Str. fecalis (65%). Str. mitis is very often demonstrable. Str. equinus prevails in horse dung (55%), and Str. salivarius in cow dung (64%). [L. H. S.]

1. Müller's article is a study of 103 cases of cervical, inguinal and axillary tuberculous lymphadenitis in the service of Dr. Frazier at the University Hospital, Philadelphia, during the past twelve years. Sixty-nine of these cases have been traced, of which 53 were cured, 9 recurred, and 7 were dead. The operative mortality was nil. He considers sources of infection and portals of entry and surgical, x-ray, and tuberculin treatment, with especial reference to scar, nerve injury and recurrence. He advocates surgery in the majority of cases, employing the x-ray only in old indurated cases preliminary to operation and after curettage of sinuses and caseous abscesses. The use of tuberculin in such cases he regards as rational.

6. Hull's communication is based upon 57 cases which he has operated upon for recurrent inguinal hernia; 45 of these occurred after an operation of this type: opening of canal, ligation of neck of sac, and suture of the conjoined tendon over the cord to Poupart's ligament. The hernia was always to the inner side of the internal ring, pushing forward the peritoneum and transversalis fascia. Seven of the 57 occurred after an operation of this type: same as former with suture of conjoined tendon beneath cord to Poupart's ligament. The hernia was always to the outer side of the internal ring. He has rarely operated for a recurrence after a typical Bassini operation. After high ligation of the neck of the sac, and amputation, he carries the stump through the internal ring and fixes it one and one-half inches above the ring. Hull regards this procedure as "probably one of the most valuable steps in the operation for radical cure of hernia."

7. White reports six cases of pain and tenderness in right iliac fossa with apparent tumor, but without fever or digestive disturbance, operated upon during the past four years, in which the psoas parvus was found in a state of contracture and projected forward into the abdominal cavity. Tension was relieved by incising the main tendon and accessory bands. No other pathology was evident and this procedure has apparently cured.

10. Steinke reports two cases of simultaneous fracture of both patellae operated upon by Dr. C. H. Frazier of Philadelphia. He has made a careful search through the literature, giving epitomies of 43 cases and tabulating 44 cases, including the two he reports, with reference to sex, age, manner and type of fracture, mode of treatment and result.

1. Allison and Brooks in a very interesting series of experiments on dogs' joints found the following conditions to develop: The denuded joint surfaces were at the end of five days covered with granulation tissue which grew from the marrow spaces. This granulation tissue developed into fibrous tissue, which later leads to fibrous ankylosis and is, according to Hoffa, the primary stage of osseous union. With the interposition of fascia lata, either in free pieces or in pedunculated flaps, the direct union of the denuded joint surfaces was prevented only in case the fascia transplant underwent necrosis and absorption. In those instances in which the flap persisted, in part, the islands thus formed acted as adhesions between the joint surfaces. There was no advantage in the use of a pedunculated flap. On the contrary, the pedicle persisted as an intra-articular band which checked joint motion. With the fascia impregnated with silver, the union of the denuded joint surface was prevented. Cargyle's membrane was absorbed within five days.

4. McKenna, as a result of dog experimentation with high bowel obstruction, makes the following deductions: Disturbance of innervation to the upper intestinal tract in the human sufficient to stop peristalsis, produces the same symptoms as mechanically blocking the same amount of intestine in the dog. High intestinal stasis, whether paralytic or mechanical, is much more serious than low obstruction. The fatal factor in acute obstruction may be found in the secretions from the duodenal mucosa. The fatal factor in general peritonitis may be due to a duodenal secretion and not to the effect of infection *per se*. When the condition of acute ileus is established early drainage of the duodenum is indicated, and this is best performed by jejunostomy.

5. Brown and Brown were unable in any experiment to reproduce bone from free periosteal transplants into the subcutaneous tissue and muscle, or to reproduce bone in the periosteal flap raised, left in contact with the bone, passed through muscle, and again contacted with periosteum. They were unable to reproduce bone in any experiment from free bone transplants, without periosteum, with the subcutaneous tissue and muscle, regardless of the size of the transplant. Absorption was the rule in every case. They were also unable to reproduce bone in a single experiment where bone was transplanted with free periosteum left intact, into muscle or subcutaneous tissue. These were also all absorbed. They were, however, uniformly able to reproduce bone when transplanted and contacted with living bone, or if it were in a position where it had a function to perform. Other necessary conditions being present for its reproduction, bone reproduces bone without the aid of periosteum. Transplants contacted with living bone and with no function to perform were inclined to absorption. Periosteum is not at all essential to the life and growth of bone as far as their work showed.

6. Cabot believes that because of greatly lessened shock and danger of post-operative lung and heart complications in suprapubic prostatectomy, spinal anesthesia is far more safe and indicated than any other form. He believes also that the usual methods of control of hemorrhage are careless and illogical, and advocates suture of the neck of the bladder as the most efficient means. With spinal anesthesia, and lessened shock, with efficient control of bleeding, the mortality from suprapubic prostatectomy will be greatly lessened, so that this method may be considered the route of election.

10. Bulkley believes that malignant disease of the abdominal testes occurs about once in 60,000 cases. About one in every four cases of malignant abnormally situated testicle is found within the abdominal cavity. About one malignant abdominal testicle occurs to each 15 malignant scrotal testicle. About one of each 75 abdominal retained testes will become malignant.

14. Cunningham believes that epididymotomy offers the best means of ending an acute epididymitis.

7. ROGERS, L. *Retractile Pointed Stop-Cock Cannula for Giving Intravenous and Intraperitoneal Saline Injections Without Incision.*

2. From a careful statistic and clinical study of dysentery cases occurring in the Raipur jail from 1896 to 1912, inclusive, Rodgers finds them of mixed causation. In the amebic cases, emetine hydrochloride proved to be the best treatment. In the Shiga cases, treatment with Shiga vaccine gave good results, but prophylactic inoculation appeared to be of even greater value. The author believes this procedure harmless, and capable of being employed also in cases where terminal dysentery is feared.

17. ADAMS, J. B. *The Doctors in the Decameron.*

1. Scott, who has made a detailed study of typhoid and paratyphoid fever in Jamaica, bases this paper on an examination of 1500 specimens of blood on which he has done the Widal reaction. As a standard he decided that a serum of dilution 1:30 should agglutinate an 18° broth culture of the organism in 15 minutes, a dilution of 1:50 in 30 minutes and a 1:100 in one hour. He is of the opinion that a careful study of the patient's history, the degree and promptness of agglutination with both the typhoid and the paratyphoid organism give important points as to the prognosis and course of the disease. These points he discusses in detail with many illustrative cases. In localities where the disease is so common as it apparently is in Jamaica such studies as these are of great value.

2. Kidd believes that there is much to be done on the subject of pus in the urine and bacterial infections of the urinary tract. In this paper he discusses methods of examination, vaccine treatment, treatment by nephrectomy, and the diagnosis and treatment of pyelitis. He deplores the air of hopelessness which has grown up around chronic cases simply because they have not been examined.

6. In this paper Patrick discusses the preparation of tuberculin, technic of administration, the various kinds of tuberculin, dilution, use in diagnosis and treatment, the various reactions, and the selection of cases and principles of dosage. The paper, while presenting nothing new, is an interesting review of the subject.

7. This paper, shorter than the preceding, covers in a very general way the same subject, *i.e.* tuberculin in diagnosis and treatment.

8. In a short article on the rational treatment of cancer, the writer concludes that surgery may cure before the period of general infection: failure in operation will be very rare if associated with fulguration, even after a limited excision: thermo-radiotherapy will intensify the deep therapeutic value of x-rays and of radium in the treatment of many inoperable tumors.

9. Monod summarizes the treatment of nephroptosis (movable kidney) as follows: (1) The use of belts which he describes, (2) free action of the bowels, (3) a diet consisting chiefly of meat, and (4) sodium bicarbonate.

13. Miller in a short paper urges practitioners to remember that not all cases of residual urine are caused by an enlarged prostate, and that many patients by proper training and persistent effort can be taught to empty their bladder and avoid a prostatectomy.

1. Eicke describes his technic for the precipitation of globulins in syphilitic cerebro-spinal fluids by colloidal gold, and gives his findings on 323 cases. The reaction is based on the fact that globulins, nucleoproteins and other albuminous cleavage products, important in causing the Wassermann reaction, are precipitated with colloidal gold at a fixed dilution above or below which precipitation does not occur. In other words, the proteins of syphilitic cerebro-spinal fluids are precipitated by gold in dilutions at which non-syphilitic fluids are not, and can be differentiated accordingly.

Eicke tabulates his results with the test as performed in the manner described. The findings paralleled the Wassermann reaction in general, but in a few cases were positive where the Wassermann was negative, although such patients developed later symptoms of syphilis of the nervous system. Eicke concludes that the gold reaction is extremely delicate and specific and affords an additional means for the early diagnosis of cerebro-spinal lues.

6. A few cases of tabes have been reported in which crises of fever occurred with or without accompanying crises of pain. No explanation has been offered for such symptoms. Siegrist adds a similar case to the literature. The patient was a tabetic who had periodic attacks of fever lasting from one to four days, with temperature reaching as high as 39°. These were accompanied by severe gastric crises or lancinating pains and passed off without treatment. Whether this symptom complex was produced by a stimulation of the heat regulating centres or by increased heat production of a nervous nature, or was due to resorption of toxines is purely speculative.

11. Meltzer and Auer in 1905 first studied carefully the physiological effects of magnesium sulphate; and its anesthetic action, following subcutaneous, intradural and intravenous administration has led to its use in tetanus. It has no specific effect on the toxin, but prevents the convulsions to a great extent. All three of the above methods of injection have been used, with gratifying results. Kocher reports six cures in seven cases. Meltzer and Auer have used a 25% solution. Kocher says that this is too strong, and that 15% is better—or even 10%. The difficult point to decide is the dose—the author says the maximum dose of the 15% solution should be 2 c.c. to 10 kilograms of body weight. Intradural injection is very effective, but must be used with great care and the patient watched constantly, so that artificial respiration and stimulation may be begun at once in the event of paralysis of the respiratory centres. This method of treatment should not supplant the tetanus antitoxin, but the two may with care be used together. The question of repeated doses depends on the extent and severity of each individual case. Auer says that "cases of tetanus in the hospital should always have this magnesium treatment." [R. H. M.]

3. This article, from Minkowski's clinic, presents for consideration a new theory of the nature of diabetes. The present ideas on the subject, says the author, are like many others in medicine, worked out backwards from the results of therapy. In a brief consideration of the present theories, he points out the objections to each.

The organs which regulate carbohydrate metabolism are the nervous system and the pancreas. The latter

is the only organ partial or total extirpation of which will always cause glycosuria of varying degrees. Experimentally, Claude Bernard has shown that trauma to the nervous system may cause glycosuria, and clinically, diabetes often follows nervous strain. The glycosurias produced by adrenalin are regarded by the author as a special instance of the Langlay-Elliot law, which states that all organs supplied by the sympathetic react to adrenalin as to irritation of the sympathetic system. The thyroid and hypophysis he regards as of secondary importance in diabetes, producing their effect probably through their action on the sympathetic.

Frank believes that diabetes is to be regarded as a disturbance of glycogen metabolism, due to the effect on the liver of derangement of pancreatic function. In support of this theory he cites the fact that anastomosis of the pancreatic vein of a normal dog to the portal system of a depancreatised dog will cause a marked diminution in the glycosuria in the latter. It is probable, he believes, that in diabetes the lack of pancreatic hormone so disturbs the glycogen metabolism that the normal chemical phenomena can no longer occur, with resultant glycosuria and acidosis. [C. H. L.]

Correspondence.

THORIUM-X.

BOSTON, MASS., Jan. 5, 1914.

Mr. Editor: The statement that has appeared regularly in the daily papers indicating a monopoly of the Thorium-X supply in this country is not true.

The Auergesellschaft, Deutsche Gasglühlicht Aktiengesellschaft, 17 Rotherstr., Berlin, Germany, will supply it so that it can reach here 1,000,000 M.E. units strength.

For my own use in the treatment of cancer, I have an apparatus making 2,500,000 units a day and from my surplus I have been able to supply a sufficient amount for the treatment of a number of cases of rheumatism and anemias, including the pernicious type.

Yours truly,

FRANCIS D. DONOGHUE, M.D.

HERTER LECTURES.

The Herter Lectures of the University and Bellevue Hospital Medical College will be given during the week beginning January 12, 1914, at Carnegie Laboratory, 338 East 26th Street, New York City. Professor Sven Hedin will lecture on "Colloids and Their Relation to Biological Chemistry."

SOCIETY NOTICES.

THE NEW ENGLAND HOSPITAL MEDICAL SOCIETY.—The New England Hospital Medical Society will hold its annual meeting Thursday, January 15, at the Hotel Lenox. Dr. S. Josephine Baker, Director of Child Hygiene Department of Health, New York City, will be the guest of honor, and will address the meeting after a buffet supper.

The business meeting will be at six o'clock, followed by a short reception to Dr. Baker, preceding the supper.

MARGARET L. NOYES, M.D., *Secretary.*

BOSTON MEDICAL LIBRARY in conjunction with the SUFFOLK DISTRICT MEDICAL SOCIETY.—Medical section meeting, John Ware Hall, Wednesday, January 21, 1914, at 8.15 P.M.. "Some Problems in Nephritis," Dr. Horace D. Arnold. Discussion by Dr. Henry A. Christian, Prof. Otto Folin and Dr. R. Fitz.

Light refreshments after the meeting.

EDWARD W. TAYLOR, M.D., *Chairman.*
LESLEY, H. SPOONER, M.D., *Secretary.*

NEW ENGLAND PEDIATRIC SOCIETY.—The twenty-ninth meeting of the New England Pediatric Society will be held in the Boston Medical Library, Friday, January 23, 1914, at 8.15 P.M.

The following papers will be read:

1. "A Case of Lymph Cyst of the Mesentery," Dr. Charles G. Mixter.
2. "The Influence of Alkalies on the Gastric Motility in Infants." Dr. Maynard Ladd.
3. "Infantile Scurvy," Dr. John Lovett Morse.
4. "The Etiology of Epilepsy," Dr. Arthur W. Fairbanks.

C. A. PRATT, M.D., *President*
FRITZ B. TALBOT, M.D., *Secretary.*

THE BOSTON SOCIETY OF MEDICAL SCIENCES.—The next meeting will be held on Tuesday evening, January 20, 1914, in the Amphitheatre of the Administration Building of the Harvard Medical School, at 8.15 o'clock.

Papers will be presented as follows:

Dr. F. H. Verhoeff: "Experimental Investigation of the Possible Therapeutic Value of Ultra Violet Light As a Germicidal Agent." (20 minutes.)

Dr. W. C. Quinby: "A Method for Crossed-circulation Experiments." (10 minutes.)

Mr. E. P. Lehman: "On the Rate of Absorption of Cholesterol." (10 minutes.)

Dr. E. G. Martin: "The Human Sensory Threshold During the Night." (10 minutes.)

THOMAS ORDWAY, *Secretary and Treasurer,*
Harvard Medical School.

RECENT DEATHS.

DR. FREDERICK C. BUSCH, who died on Jan. 3 of vesical carcinoma and terminal pneumonia at Buffalo, N. Y., was born in 1873. He was assistant superintendent of the Gratwick Cancer Laboratory, and professor of physiology at the University of Buffalo.

DR. BENNO A. HOLLENBERG, of New York, died on January 1. He came to America from Germany in 1860, and, having taken up his residence in Huntsville, Ala., he served for most of the Civil War in the Confederate Army. He was graduated from the College of Physicians and Surgeons, Memphis, in 1885, and had practised in New York since 1893.

DR. JAMES A. H. CURTIS, who died last week in Paterson, N. J., was born at Brampton, Canada, in 1877. He was a graduate of Albert College, Ontario, and of Trinity University, Toronto. He served for two years as house surgeon at the Paterson General Hospital, and subsequently settled in the practise of his profession at that city. He was a member of the New Jersey State and Passaic County Medical Societies. He is survived by his widow and by one daughter.

DR. FRANZ REDER, who died on Dec. 28, at St. Louis, was born in Mellrichstadt, near Munich, Bavaria, on March 14, 1829. After studying at the Universities of Munich, Würzburg, and Heidelberg, he migrated to the United States in 1860. He is survived by two daughters and three sons, two of the latter being also physicians.

DR. ANDREW FLINT SHELDON, who died on Jan. 4 at Lyons, N. Y., was born in 1829. He served throughout the Civil War successively as assistant surgeon of the Seventh New York Cavalry and of the Seventy-eighth New York Infantry, and as executive staff-officer in the medical director's office at Washington, D. C. After the war he was brevetted lieutenant-colonel. He was an originator of the field hospital tent.

DR. GEORGE EPHRAIM FULLER, a retired Fellow of The Massachusetts Medical Society, died at his home in Monson, Mass., Dec. 23, 1913, aged 74 years. He was a native of Wilbraham. He left Amherst College in 1861 to enter the Army and served altogether four years and seven months in the cause of the Union. He had practised in Monson since 1868 and at the time of his death was president of the Monson National Bank. He died suddenly of heart disease.

Original Articles.

MORTALITY OF HEREDITARY SYPHILIS.

BY ABNER POST, M.D., BOSTON.

SYPHILIS is declared by writers on the subject to be simply murderous in its hereditary manifestations.

The distinguished syphilographer, Fournier, gives the statistics of 500 syphilitic families with whose history he is acquainted, as follows: In 223 families no transmission of the disease to offspring has taken place, in 277 families such transmission has taken place.

In these 500 families, 1127 pregnancies have occurred, 600 children are reported living and well; 527, or 46%, of the pregnancies have resulted unfortunately, as follows:

Abortions and still births	230
Early deaths	245
Living and syphilitic	38
Mentally deficient	14
	527

There is a tendency to disregard syphilis in this country. It is supposed to be a disease of older countries and rare in this; it is thought to be confined to those who go to seek it and to have no interest for those whose lives are blameless. If one accepts the death returns of the country as final, one may well say that the fatalities from syphilis are negligible.

It is the good fortune of the Boston Dispensary to have in the Dermatological Clinic a large number of syphilitic children, who furnish the material for this paper,—which concerns itself chiefly with those victims of hereditary syphilis who have survived the perils of infancy. Most of those who are considered have passed the earlier period of second dentition. They range from five or six to eighteen or twenty years of age.

If one looks at the vital statistics of Massachusetts, where these children have been seen, syphilis will be found notoriously absent, hardly more important in numbers than leprosy or typhus.

But it must be remembered that no one dares to assign syphilis as a cause of death. It would probably cost a doctor his popularity and ruin his practice if he dared to append that cause of death with the same simplicity that he would write typhoid or pneumonia. One must look elsewhere than at the official death returns to know anything about the fatality of syphilis.

From the children with hereditary syphilis who appear at the Boston Dispensary Clinic, it is our custom to learn all that we can in regard not merely to the patient, but also in regard to the family. This information is obtained usually from the mother or relative who brings the child. We have tried to learn the number of deaths in the family, with the alleged causes of death, and the condition of the survivors, and in regard to the patient, enough of the life history to know how far he or she falls short of the perfect child by reason of the syphilis.

It has not been possible to analyze all our material. It is only within a short time that our records have preserved material of this sort, and in regard to many families the records are of necessity quite vague. The mortality in 30 syphilitic families has been tabulated with the following results:

In these 30 families there have been 168 pregnancies; of these pregnancies there have been 53 still births and miscarriages, and 44 early deaths—a total of 97 lost, or 57%—71 remain alive.

57% of the pregnancies are dead.

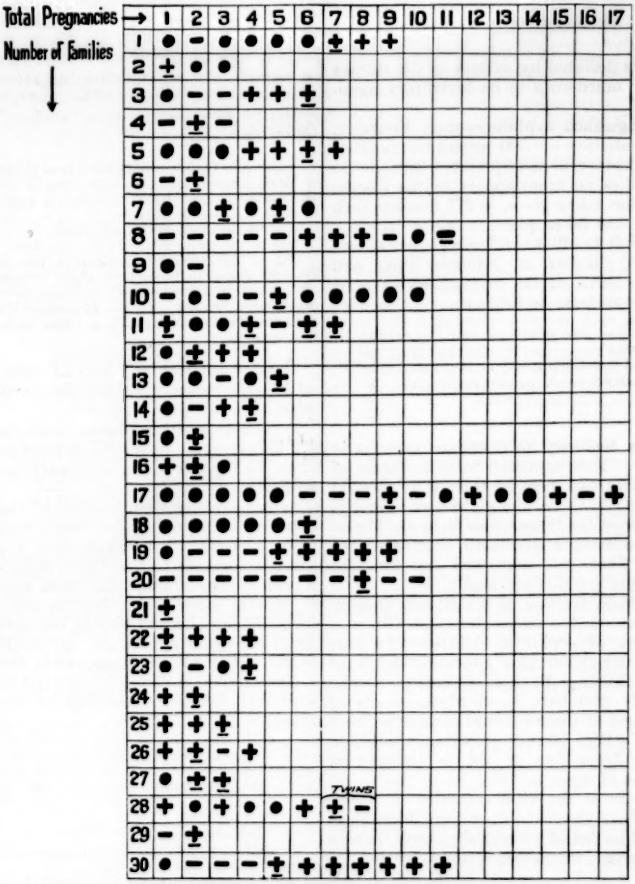
38% of the children born alive are dead.

Out of the 168 pregnancies, of the 115 children brought living to the world, there remain alive 71; of these 71, 32 have been our patients, leaving only 39 presumably healthy. In the accompanying chart our patients are represented by a cross with a straight line beneath.

It is of interest and also of value to know what is the reason for this great mortality, or of what these children die.

Probably no other disease presents the same sad history as syphilis. No attempt is anywhere made, so far as I know, to classify the causes of stillbirth.

It has already been mentioned that syphilis appears infrequently in death returns as a cause of death. It becomes, then, a question of some importance to know how these deaths are reported, for certainly they must appear on the returns in some form. No one can for a moment believe that syphilis is the only cause of death in syphilitic families. Syphilitic children readily fall victims to intercurrent disease.



The attributed causes in 86 fatal cases in our syphilitic families, according to the mothers' accounts are as follows:

Congenital syphilis	2
Uncertain	4
Cholera infantum	25
Marasmus	27
Pneumonia	5
Hydrocephalus	5
Spinal meningitis	5
Scarlet fever	4
Chickenpox	2
Measles	2
Furunculosis	1
Diphtheria	1
Gastritis	1
Bronchitis	1
Accidental death	1

Of these causes, 25 cases of cholera infantum may, perhaps, be regarded as cases in which another disease is superimposed on a syphilitic basis, though it may be that the death could just as well have been attributed to syphilis as to cholera infantum.

Twenty-seven cases of marasmus is a striking number. Wasting is a symptom not at all un-

common in inherited syphilis and it cannot be far wrong to say that the symptom of marasmus is utilized to cloak the underlying disease.[1]

In regard to the five cases of pneumonia, it must be said that a form of pneumonia is found in syphilitic children. It is syphilitic in character but it may very well be used as cause of death either from failure to recognize the underlying syphilis or purposely to hide it.

Hydrocephalus is caused by syphilis as well as by other diseases, and we are justified in believing that hydrocephalus occurring in syphilitic families is of syphilitic origin.

The diagnosis of spinal meningitis may be regarded with suspicion in this connection.

It is pretty certain that the returns for marasmus, pneumonia, hydrocephalus are falsified by reporting as such some deaths which might more properly be returned as syphilitic. How far the returns of cholera infantum are vitiated, if at all, nobody can tell. No one can for a moment believe that syphilis is the only cause of death in syphilitic families. It must be recognized that the vital resistance of these children is greatly reduced by their heredity and they readily fall victims to intercurrent disease.

Among the families introduced to our notice, but not registered in this table, are several where the disease has entered the family after the birth of one or more healthy, that is, non-syphilitic children. The contrast in mortality in these families between the earlier healthy and the later syphilitic children is very striking and seems to emphasize the fatalities due to syphilis. The earlier children show only normal death-rate, while the later show the abnormal death-rate of syphilis.

Occasionally it happens that the first child survives with signs of hereditary syphilis, while the following pregnancies end fatally. These are families in which the husband is syphilitic at the time of marriage, but not in a condition to inoculate his wife. The first child is the product of a syphilitic father and a healthy mother, and its chances of surviving are better than that of the children who immediately follow after the mother has passed through the first pregnancy and become herself syphilitic.

These 30 families were introduced to us by children who came as patients for their own bodily ills. So far we have considered the families from which they have sprung. The patients deserve our study for their own sake. They are the survivors of the numerous fatalities. Each one suffers from the inherited disease in such a way as to make him seek for medical aid, and no two are alike. Heredo-syphilitic children present an almost endless variety of symptoms, in an endless variety of groups.

[1] This note is taken from the Physicians' Pocket Reference to the International List of Causes of Death issued by the Census Bureau. "Marasmus." This term covers a multitude of worthless returns, many of which could be made definite and useful by giving the name of the diseases causing the marasmus or wasting. It has been dropped from the English Nomenclature since 1885. ("Marasmus, term no longer used.") The Bellevue Hospital Nomenclature also omits the term.

In the first place, the heredo-syphilitic child is unfinished. It is less in size and weight than normal. It is three or four years behind the normal children of its age. This incomplete, unfinished condition may be evident in the child as a whole or in any part of it. To the condition as a whole is applied the term infantilism.

The internal organs are abnormal in the same way. As these children come to us, they show their hereditary deficiencies in various degrees and also the stigmata of infantile disease. At the same time with this deficient development, there occur in some an increase in bony structure, the deposit of new bone in some circumscribed spot. Its forehead may be increased in size in various parts so that it has a projecting and abnormally large forehead. Some of the long bones have bosses or circumscribed swellings.

Of the children seen during the last year, by far the greater number were suffering from partial blindness, temporary in most of them. The number of cases of eye disease in this particular group was abnormally large because they had come primarily from an eye clinic. One of them was at the Blind Asylum, one at the Kindergarten for the Blind. All of them were unable to attend school for months at a time. One of them came from the Horace Mann School for the Deaf and Dumb.

Several are deaf, one or two completely or nearly so to ordinary conversation. Many have had operations for the removal of tonsils and adenoids. There is room for the suspicion that some of the operations, and especially the repeated operations for adenoids, done on syphilitic children, are unnecessary. The narrow nasal passages and the swollen mucous membranes of the syphilitic child occasion the same symptoms as adenoids, and the first treatment should be for the syphilis, and only when that is found unsatisfactory, the operations for adenoids.

Many children in this number are mentally deficient to a much less marked degree. Most of them are backward in school because of their various physical defects. It is by no means an easy task for a clinician to know exactly how to classify the mental condition of these children. We hope to have them studied at some future time by expert teachers.

Active processes of the disease may be still going on in various parts of the body, nose, throat, legs, eyes, ears, lymphatic glands, bones as well as internal organs,—heart, lungs, nerves and other organs. For each one of these troubles the child has ordinarily sought relief in the clinic devoted to the special organ affected. Without knowledge of the other affections or the child's history, it is often extremely difficult in these various clinics to recognize the underlying taint which is the real cause of the trouble. At these various clinics these children are treated for their various ailments, but when all has been done for their eyes or ears or throats

that can be done in the special clinics, they are discharged, very properly, but the child still needs treatment for its constitutional condition, which it does not always receive. The children, as we see them, have usually a history of visits to many clinics, where, for a time, they have been the object of care, but with the advent of new symptoms they betake themselves to some new clinic and to new physicians.

A few detailed histories will be worth any amount of description. (See accompanying chart.)

J. C. No. 1, is the result of the seventh pregnancy. The first was born dead; the second lived eight months; 3, 4, 5, and 6 were born dead. John, the seventh, is 12 years old. The eighth and ninth are also living. John, our patient, has been put back in school a good deal because of sickness; has had two operations for adenoids; has glands on the neck said to be tuberculous, but probably due to decayed teeth. He applied at the Eye and Ear Infirmary for interstitial keratitis believed to be syphilitic. He has characteristic syphilitic teeth and slight deafness. He is said to be without ambition and would like to sleep most of the time.

M. S. No. 12 on the chart, was referred to us from the Eye and Ear Infirmary for our co-operation. She is the oldest child of four, only one has been lost. Mary was a seven-months' baby. For a long time had no finger or toe nails. At one year, had pneumonia; at two, nasal obstruction. No teeth until four years old. Did not walk until 3½. Six months ago had severe pain in right leg. Is behind in school. Mother volunteers that Mary is not very bright.

In addition to interstitial keratitis, Mary has scars about mouth and nose believed to be due to syphilitic lesions in infancy. Characteristic syphilitic teeth. The pain in her leg was due to syphilitic periostitis, which is easily recognizable and which kept her awake the night before her visit to the Dispensary.

These surviving children are well worthy of recognition by those interested in diminishing infant mortality, for they furnish the explanation of the death-rate in their families which otherwise might not be recognized. Some of the survivors live to become fathers and mothers themselves. How far they are able to transmit the disease to their own offspring is uncertain, but certainly many of them are unfit to become parents whether they actually transmit syphilis or not. From their undeveloped brains and bodies one cannot expect a very high class of citizens.

They are but examples from a large attendance at the clinic. The seriousness of the group, as it concerns the general welfare, depends largely upon the total amount of syphilis in the community. There is no census of syphilitics nor is one possible at present, but there have been attempts made to approximately learn the amount of the disease in the country. The figures fall between 15 and 20%. It is, then, from its numbers, of no inconsiderable importance, but the failure to rightly report syphilis means an addition in the report of something else. It falsifies the returns.

It would not be just to leave this subject without drawing attention to the fact that the transmission of syphilis to children is not universal. Many children of syphilitic parents are born without any taint of the disease. In the table quoted from Fournier at the beginning of this paper, it was stated that of 1127 pregnancies in 500 syphilitic families, 600 children were reported as living and well. In addition, it must be noted that time and treatment have great effect in mitigating the evil. One patient at the Boston Dispensary, a man of perhaps fifty, himself the victim of late lesions of syphilis, gave a history of his family as follows: the first child was stillborn, the second died in infancy, the third is living and the fourth is a young man in the United States Navy—a position which presupposes good health, both in mind and body.

And, now, this paper would be incomplete without a word as to the study of the disease as a whole. It is usually spoken of as a venereal disease and syphilis and gonorrhea are classed together. These two diseases are entirely separate and distinct. They owe their existence to two entirely different microscopic organisms which have no relation to each other. They need to be studied as distinct diseases and not as evidences of immorality. The physician must do his share in their prevention and control quite as much as the moralist. Syphilis is an infectious disease—conveyed by the most innocent kiss or even careless handling. No one can for an instant think of calling the children referred to in this paper sinners. Probably at least half of the syphilis in the world is innocently acquired and even the sinners are our brethren.

The desire to attach disgrace to all victims of the disease leads to concealment and difficulty in study. If we are in any way to control the disease, it is necessary to have a moderately accurate knowledge of it. The more we know of syphilis, the more formidable do its possibilities appear. The many fatalities and the possible diseases which may affect the survivors, as well as the good that may be done by supervision and medical care, not only in the way of prevention but in the amelioration and possible cure of the afflicted, it is the object of this paper to point out.

MASSACHUSETTS ANTI-TUBERCULOSIS LEAGUE.—Under the auspices of the Boston Association for the Relief and Control of Tuberculosis a meeting was recently held to organize the various tuberculosis societies of this State, now thirty-five in number, into a single central body, to be known as the Massachusetts Anti-Tuberculosis League.

A CASE OF MYATONIA CONGENITA (OPPENHEIM).

BY J. W. COURTNEY, M.D., BOSTON,

AND

H. B. EATON, CAND. MED., BOSTON.

ALTHOUGH thirteen years have elapsed since the clinical manifestations of this extraordinary disease were first described, the total number of cases on record to date is not large; consequently, we feel that this contribution may be offered without apology.

The patient is a boy of five and a half years, of healthy parents, both of whom sprang from sturdy New England stock. During the pregnancy, which terminated in an instrumental delivery at the seventh month, the child's mother felt what she assumed to be normal fetal movements. Her health was good all the while except for rather persistent and troublesome pains which she attributed to rheumatism. The birth of the patient ended the first pregnancy, and he is the only child. There have been no miscarriages.

The weight at birth was less than three pounds, and the child's head, although well-shaped, was markedly large in proportion to the body. Also, it was noticed that from the moment of birth the head tended to fall backward on the shoulders and that the neck muscles were "like jelly."

The child nursed after the first three or four days, but lay for months in a stereotyped position which strongly suggests the fetal, *i.e.* with arms folded and the feet so intertwined that the plantar surface of each was in apposition with the opposite tibia. At the outset the muscles generally are said to have been flabby in the extreme, but the disability of the lower extremities was greater than that of the upper and the proximal portion of the limbs was more affected than the distal. If an arm got extended and abducted the child could not voluntarity flex and adduct it, and vice versa. There was no apparent disturbance of intellect or special senses, the breathing was never hampered in any way and the bowel and bladder emptied themselves in normal fashion. Teething did not begin until the eighteenth month, but then progressed rapidly. Prior to this time the child could say "papa, mama," and a few other words.

The case was first seen by one of us in July, 1911. At that time the child's habit was to lie upon the belly. It could neither sit nor hold the head erect. When it was placed in the sitting position and supported under the arms, the spine showed a very marked kyphoscoliosis and the head fell backward and to the right. There was more or less constant drooling; nevertheless, the intellect was in nowise below par and the patient showed the usual quota of cunning traits peculiar to children at that age. The speech was somewhat difficult of comprehension, but the vocabulary was normal. The head was noticeably large but well proportioned, the fontanelles were closed, the eyes clear and alert, the facial expression mobile. The pupils were equal, regular in outline and prompt in their response to light and distance. The facial and ocular muscles, tongue and soft palate were normal, likewise deglutition. The tracery of the temporal veins in the somewhat pallid skin was rather striking. The respiratory movement was not restricted; the heart area and sounds were normal, the pulse in no way remarkable. All the tendon reflexes were absolutely unobtainable. The epigastric, belly, cremasteric and plantar reflexes were present but sluggish, in fact, cutaneous sensibility in general seemed rather below normal. There was no rosary and no epiphyseal enlargements.

The most striking feature of the case was the motor impotency of the child and the muscular conditions which underlay it. Everywhere the muscle-bellies seemed thin and flat, but, nevertheless, did not for a moment give the impression of a true atrophy of spinal or neuritic origin. The thinness was most marked throughout the right half of the neck posteriorly and the right side of the back. This accounted for the falling of the head backward and to the right and for the kyphoscoliosis respectively.

Very striking was the poverty of muscle-fibre—and we may add subcutaneous fat—in the arms. The chest and belly muscles seemed fairly adequate. Those of the thigh and leg were even more normal in contour and consistency than the last named, but utterly incapable of contracting voluntarily with any degree of vigor. It is to be regretted that no neuro-muscular electrical tests were made at this time.

The patient was ordered five grains of calcium lactate suspended in milk three times daily, and directly following the visit was taken to the seashore where it had the advantage of out-door life and sea-bathing. The progress made was most satisfactory. At the end of six weeks the child could sit up alone, although the head still fell backward and to the right and the kyphoscoliosis was extreme. At this time, also, the knee- and ankle-jerks were present and the cutaneous reflexes fairly prompt.

During the winter of 1912 codliver oil was steadily given and the dietary and hygienic conditions carefuly attended to. The acquisition of muscular strength was constant. Before the end of the winter the child could sit in a chair and cross his legs and, by holding on to his mother's hand, could take a few steps. He gained noticeably in weight and drooled only when very tired.

In March, 1913, the patient developed chicken-pox which was followed by diphtheria. He was ill five weeks and lost ground considerably in consequence, but fortunately escaped a post-diphtheritic paralysis. After this illness he was taken to the sea-shore where he gained to such an extent that in September he could use his hands fairly well, walk about the room unassisted and make his way over the stairs.

At the present time, last of October, 1913, the boy is well-nourished and has good color. He is bright and alert mentally and his articulation is fairly clear. He drools only when very tired. Height 42¾ in., weight 38½ pounds. The head, which still tends to fall backward and to the right, shows the following measurements: circumference 53 cm., ear to ear over sinciput 34 cm., glabella to inion 33 cm. The gait is extraordinary and difficult to describe. Before starting to cross a room the boy stands in an attitude which suggests that of a sprinter on his mark. One arm is thrust directly in front of him, the other behind. The gait is a mixture of ataxia and steppage and, withal, there is in it a suggestion of the peculiar vibratile quality observed in that of multiple sclerosis. The head waggles concomitantly. Once started the patient seems unable to stop until

some obstacle is encountered. Station in the Romberg position is impossible; with the eyes open and the feet apart there is no special swaying, but the knees are markedly hyperextended and the right foot pronated. The pupils are middle-wide, equal, regular in outline and normal to tests of light and distance. The facial and ocular muscles, tongue and soft palate are normal. Fundi healthy. The heart and lungs are normal. Chest circumference 52 cm. The spine shows a lesser degree of kyphoscoliosis. It is the child's wont to keep the fingers flexed in the palm with the thumb underneath, but there is absolutely no spasm or contracture. The finer coördinative movements of fingers and hands are quite impossible. For example, the boy cannot deftly pick up even the plug of a small Faradic battery and insert it in its orifice. In the attempt to perform the latter part of this feat the hand gyrates about the orifice in circles of varying circumference, but the goal is never attained. Meantime the head waggles concomitantly, precisely as it does when walking is attempted. Nevertheless, with solid foods the patient feeds himself fairly well. The musculature of body and limbs has developed fairly satisfactorily both in volume and strength, but the local disproportions noted above are still in evidence. Curiously enough, neuro-muscular response to even mild Faradic stimulation is everywhere equally prompt. The deep and superficial reflexes are all normal.

It requires no special diagnostic acumen to differentiate a typical case of myatonia congenita, like the above, from other conditions which, in a limited number of features, resemble it. The peculiar character of the muscle defect, the fact that this defect is present in its maximum intensity at or shortly after birth, and the further fact that the morbid process is regressive all combine to distinguish this process from whatever underlies all other myopathies and spinal atrophies, and to place upon its symptom-complex the cachet of a genuine clinical entity.

It will be remembered that Oppenheim[1], entirely without the support of pathologic data, believed, at the time he first described the disease in question, that an incomplete genesis of the muscular system was the essential underlying morbid factor, although he did not absolve the anterior horn cells from all connection with this retardation of muscular development. As a matter of fact, actual pathologic investigations, although few in number, seem, in the main, to bear out the Oppenheim theory. We shall refer, however, without prejudice, only to the article of Archangelsky[2] and Abrikosoff, because their case seems to us clinically typical and, at the same time, we are strongly impressed by the completeness and apparent exactitude of their pathologic findings.

These observers report the case of a female infant who came under the observation of one of them (Archangelsky) at the age of three and one-half months. The child's parents were disturbed by its slow gain in weight (only one pound in three months) and its inability to move the limbs. The child looked anemic; the nutritional state was satisfactory (!); the vertebral column of normal configuration. The thorax was deformed to a marked degree—the sternum protruded sharply, and the chest walls were so sunken that on inspiration the middle portions of the ribs of one side appeared to rub against those of the other. The borders of the lowest ribs were prominent. There was no rosary. The belly was big and flabby, and in contrast to the narrow thorax appeared really enormous. The respiration was clearly diaphragmatic. On inspiration the belly increased in size to a marked degree. The respirations were seventy to the minute and were associated with strong retractions in the region of the insertion-points of the diaphragm.

The most striking feature of the case was the almost absolute immobility of the child. When taken from its bed and placed upon a pillow it assumed a whining expression, while the entire body, extremities and head remained entirely motionless.

The characteristic position of the child was that of a person crucified. The legs were extended, the arms abducted and somewhat flexed at the elbows, the hands resting upon their ulnar borders, with the little fingers bent in such a way that they almost came in contact with the outer side of the corresponding fifth metacarpal bones.

With the child raised in the vertical position the head fell limply and indifferently either forward or backward. Passive motion of the limbs could be carried to almost any extent without apparent pain. Voluntary contraction was limited to one or two muscles and was feeble and restricted in extent. For example, sharp pricking of hands and feet caused but slight movement of the distal portion of these extremities. The child seemed alert to what was going on about it and the excursion of the eyeballs was not limited. The pupils were equal and prompt to light. There was no nystagmus, and the muscles of the face, tongue, soft palate and pharynx were normal. The hearing seemed undisturbed, and the voice was clear but weak. Internal organs healthy. The tendon reflexes were entirely absent, likewise the plantar. The exact status of general sensibility was difficult to determine. While the other muscles were scarcely palpable; both biceps felt like thin, somewhat tense, strings.

The family history was negative, and the child's mother stated that the pregnancy was normal, although throughout the entire second half of it fetal movements were but feebly felt. The birth itself took place at the regular time and was normal in every way. No instruments were used. The weight of the apparently normally-developed newborn was 8½ pounds (3½ kg.). Its exact condition during the first month of life was difficult to determine, although the concensus of opinion of those concerned with its care was to the effect that during this period not even the slight movements of the fingers observed in the second month were present. At the beginning of the second month an electrical examination disclosed a complete lack of response of the muscles everywhere on neck, trunk, and extremities to even a very strong Faradic current.

Toward the end of the third month of life the child began to lose rapidly in weight and the loss continued up to the time of its death, which came suddenly, about the middle of the fourth month, from acute pneumonia. Archangelsky was astonished to observe that in spite of the marked and progressive loss of weight, voluntary motion steadily increased. Only the week before its death the child, lying supine, could move its head sidewards to some extent, and could, when supported in a vertical posi-

tion, maintain the head erect for several moments. It was also able to raise the hands to the mouth and, with the knees bent, to abduct and adduct the thighs.

The necropsy, made sixteen hours after death, may well serve as a model for all future investigators. Not an organ, not a shred of tissue that might throw a ray of light on the pathology of myatonia congenita was neglected. Macroscopically this searching investigation revealed only the following abnormalities: (1) Varying degrees of hindered development, pallor and flabbiness of all the voluntary muscles; (2) Pial edema throughout brain and cord (3) Moderate venous engorgement and edema throughout the tissues of cerebrum, cerebellum and cord; (4) Unusual thinness of ventral roots throughout the cord, but most marked in the lumbar region; (5) Catarrhal broncho-pneumonia and (6) Ovarian cysts of varying sizes. The anterior fontanelle was wide open, and all signs of rachitis were lacking.

The detailed description of the microscopical examination is too long to reproduce in its entirety. From the side of the nervous system the findings were, briefly, as follows: (1) A persistance of the remains of the peripheral granular layer of the cerebellum. Incidentally, this may be regarded, in part, as an individual peculiarity not infrequently encountered at the age in question; (2) An incomplete myelinization of the pyramidal tracts and Gower's bundle—both structures in which the fibres are not ordinarily fully myelinized until after birth; (3) Absence of the normal nerve-cell grouping in the posterior horns (absence of Clarke's column), with presence in these parts of numerous small multipolar cells; (4) In the lateral horns substitution of many small multipolar cells for the usual large cells; (5) In the anterior horns marked reduction in the number of nerve-cells, with entire absence of large ganglion cells and presence of a few scattered small multipolar cells. Here all nerve-cells appear small, as shown by diminished size of cell-bodies, nuclei and nucleoli. No signs of degenerative changes. The number of nerve-fibres in the gray matter is reduced and the majority of them lack myelin sheaths: (6) In the lateral anterior roots numerous amyelinized axis-cylinders and empty neurilemmata, together with cylinders which are myelinized but thinner than normal; (7) In the median anterior roots nearly complete absence of myelinized fibres, with a peculiar swelling of the amyelinized; (8) In the peripheral nerves a combination of myelinized and amyelinized fibres, with empty neurilemmata. No actual degenerative changes.

In the muscular system the following findings are recorded: "All the voluntary muscles, with the exception of the diaphragmatic, facial, pharyngeal and laryngeal, are very slender in consequence of the extremely marked thinness of the majority of the within-retained muscle-fibres; there are no signs of gradual muscle atrophy, no proliferation of nuclei, interstitial connective or fat tissues."

As Archangelsky and Abrikosoff view the problem, the question to be resolved, as far as the nervous system is concerned, is whether we are dealing with absent or impaired development of the gray substance of the cord, anterior roots and peripheral nerves or with an actual degenerative process in the same. For these authors the absence of the normal nerve-cell grouping of the gray substance, the complete absence of Clarke's columns, the great number of cells in the substantia Rolandii (suggesting embryonal conditions), further, the presence of very numerous multipolar nerve-cells irregularly distributed in the gray substance of the lateral and posterior horns—all may indicate an interference with the normal distribution and growth of the nerve-cells. On the other hand they point out the fact that the primary development of the ganglion cells of the anterior horns begins very early (before the fourth embryonal week) and hesitate to explain the absence of these cells on the ground of hindered development, because it seems to them highly probable that the hindering process would also exert a deleterious influence upon the development of the horns themselves. They recognize, moreover, the existence of atrophic processes in nerve-cells characterized by diminution in size or even by complete disappearance, without grave change in their structure. This fact complicates the solution of the problem, even though not all the changes found can be attributed to such an atrophic process.

The character of the changes in the nerve-fibres in the gray substance is regarded as of no importance in the solution of the pathologic problem, since these changes could equally well come either from hindered development or from atrophy of the nerve-cells.

Of far greater importance to the above-mentioned authors is the character of the changes in the anterior roots and the peripheral nerves. They note that in spite of the small content of myelinated fibres and of axis-cylinders deprived of their sheaths (lateral groups) and, further, in spite of the almost complete absence of the same (median groups), the mass of roots in its entirety does not seem to be correspondingly diminished but, to a certain degree, retains its normal area. They note, furthermore, that on cross sections of the roots a mesh-like structure is apparent, whose lumina and the arrangement thereof point absolutely to absent nerve fibres. And from this circumstance they conclude that, beyond all doubt, at least a part of the nerve-fibres of the anterior roots have undergone some sort of degenerative process and disappeared, leaving behind only empty nerve-sheaths.

From the above pathologic data Archangelsky and Abrikosoff conclude, finally, that two kinds of changes are present in the spinal cord; 1. A hindered development of its gray substance—as shown by the lessened dimensions of the cells of the lateral and posterior horns, the interference with the customary grouping-process of these cells, the thinness of the myelinized fibres and the axis-cylinders of the anterior roots, the absence of myelinization of the majority of the nerve-fibres of the gray substance, anterior roots and peripheral nerves and the embryonal appearance of the substantia Rolandii. 2. Degenerative changes of the cells (simple atrophy)—as shown by the failure, for the most part, of the cells of the anterior horns and

the disappearance of a portion of the nerve-fibres in the anterior roots and peripheral nerves (empty neurilemmata).

The changes in the muscular system are unhesitatingly ascribed by Archangelsky and Abrikosoff to hindered development (hypoplasia) of the muscle-tissue, as evidenced by the uniform thinness of the muscle-fibres—with complete preservation of their structure—and the absence of nuclear proliferation and increase of interstitial tissue.

A point much more difficult for these authors to make clear to their entire satisfaction is the connection between the hindered muscle development and the changes in the spinal cord. They finally conclude, however, that the paralysis and atony of the musculature spring from hindered development of all peripheral motor neurons, but chiefly from a hindered development of the muscle-tissue, which is contemporaneous with that of the cord. The disappearance of the feebly developed anterior horn ganglion cells they regard as secondary and as a result of the consecutive atrophy of these cells.

To the present writers the term—myatonia congenita—seems satisfactory from a clinical standpoint, for the reason that the muscular atony which characterizes it does certainly dominate the picture. On the other hand, the pathology ascribed to it by Oppenheim and subsequent observers impresses us as too narrow in conception.

Its exact pathogenesis must, for the present at least, remain shrouded in obscurity. We venture to suggest, however, a probable correspondence between its pathogenetic factors and those which act upon the primary embryonal tissues in such a way as to bring about spina bifida or hare-lip. Just how early in fetal life the developmental activities are arrested we do not pretend to say. Archangelsky and Abrikosoff, in their case, found muscle-fibres morphologically and structurally identical with those ordinarily observed in the third or fourth fetal month, while our own case has, so far as we know, the distinction of being the first to exhibit the typical picture of the disease at the end of the seventh.

Our reasons for considering the reigning pathologic conception of the disease too narrow are, in part, derived from the microscopic studies of others and, for the rest, from personal clinical observation. In our case, for example, the impaired articulation and the drooling show that the brain-stem, as well as the cord and peripheral nerves, is involved. Furthermore, the marked disturbance of equilibrium observed by us makes it clear that inhibition of sensory neuronal development is also to be reckoned with. This fact alone proves that the theory of hindered development of peripheral motor neurones and muscle-tissue does not cover the whole pathology of the disease. We feel that it may be that the impaired equilibration is due to the absence of Clarke's columns, and we would urge future investigators to keep this interesting point prominently in mind.

As to prognosis, the reported cases show that the mortality is rather high—about 30%—and that pneumonia is the commonest cause of death. Our case may be classed among the most favorable, but even here complete restitutio ad integram seems to us out of the question, when we consider that the pathology embraces atrophy and disappearance of anterior horn cells and peripheral nerves.

Treatment consists, in the main, in the administration of tonics—we found codliver oil and calcium lactate most serviceable—massage and electricity. Among other important therapeutic measures, warm sea-bathing, generous diet, open-air life and simple coordinative exercises should be mentioned. On general principles, artificial support of the atonic muscles by apparatus should be avoided.

THE SUSPICION OF MALIGNANCY.*

BY HOWARD LILIENTHAL, M.D., NEW YORK,

Attending Surgeon to Mt. Sinai and Bellevue Hospitals.

NEXT to hemorrhage there is probably no abnormal phenomenon which is to the patient himself more disquieting than the appearance of a tumor. Even with a brave though foolish attempt to disregard the unwelcome presence, and by ignoring to drive it away, there is still the almost subconscious dread that after all we may be facing that ominous, that malignant thing which we know and fear as cancer.

What comes next will depend upon the temperament of the patient; and the human soul is ever individual and never duplicate.

In general, people may be classified as timid or courageous. Yet when confronted with this dreadful spectre of malignancy it is not always the coward who shrinks from the scalpel nor the brave man who seeks the prompt aid of the surgeon. Indeed, the timid are often the first in very panic to seek operative relief, while I have known at least one noble-spirited man, who, with the full understanding of what delay would mean, put off for a year the operation which might have saved him, so that his wife, herself the victim of fatal cancer, should be spared the knowledge of her husband's peril.

The average individual, alarmed at discovering a tumor, will lose little time in consulting his doctor; and often enough his future will hang upon the tactful and conscientious quali-

* Read before the Worcester District Medical Society, Wednesday, December 10, 1913, at Worcester, Mass.

ties of this first adviser. And the task of the physician here is no easy one. Should the case prove at a glance to be free from suspicion, his words will bring comfort and gratitude, the good news in some way reflecting upon the physician just as if he were in a manner responsible. But when warning of possible evil must be given then indeed is demanded the utmost delicacy in the management and direction of that complex and contrary force, the mind of man. Too often it is proved that "The bearer of ill news hath but a losing office," and the well-meant efforts of the honest practitioner are repaid with charges of brutality or, even worse, commercialism. Possibly ths patient will seek another and more favorable opinion at the establishment of some one whose code of ethics will not forbid his keeping the sufferer in a fool's paradise until the opportunity for cure is past. The temptation to temporize is therefore great, and when there is nothing more than the mere suspicion of malignancy it is easy to give a placebo and to request the patient to return in a week or in a month, so as to lessen the psychic shock. But that patient may gradually become, as it were, accustomed to his disease, strange as it may seem, and his suspicion having been partly lulled, his second visit may be put off until certainty has taken its place—and with that certainty of diagnosis comes the greater doubt of cure.

But suppose a case is one of those obscure ones in which the diagnosis can be hoped for only after repeated careful examinations. Here, instead of making a tentative diagnosis, the patient should be told frankly that further observation will be required and that he must have patience.

There is perhaps no greater mark of the scientific clinician than the method and completeness of the physical examination. And nothing so educates the physician as the oft repeated and careful inspection, palpation, auscultation, percussion, with the noting of change in the progress or retrogression of the disease.

You have all heard this over and over again — yet how often are the more troublesome examinations put off until the appearance of some danger signal which cannot be disregarded.

Take, for example, that most frequently neglected procedure, the digital examination of the rectum. There is hardly a surgeon who has not had thrust upon him the sad duty of announcing the presence of inoperable rectal cancer, and all because in a case of obscure diarrhea no one made this simple exploration until it was too late. And yet, in any irregularity of the bowels, rectal palpation should be one of the first diagnostic steps instead of the last, the proctoscope supplementing the negative finding of the finger. And the youth of the patient is by no means a scientific reason for ruling out malignancy in this region.

Within the past year I have seen in my practice two fatal cases of inoperable rectal carcinoma in young women under twenty years of age! And these patients could almost certainly have been saved had the disease been earlier recognized, for the cancers of the rectum are of comparatively low malignancy.

The discovery of one morbid condition which ever so completely explains the symptoms of a disease does not mean that we are to neglect further inquiry. This appears to be self-evident, yet the following case will demonstrate how easily one may err.

CASE. A young man about 35 years old came to me with a painful nodular and movable mass the size of a small adult fist, in the right mid-abdomen. There had been deterioration in health for some months, but there were no symptoms referable to disorder of the digestive tract. The growth seemed one which could be easily removed and I referred him to my service in Mt. Sinai Hospital. Simply as a matter of routine, the gloved finger was inserted into the rectum, when at once a non-obstructing though obviously malignant tumor of great size and totally inoperable was discovered, the abdominal mass being evidently secondary.

The presence of hemorrhoids does not signify that the rectum higher up is healthy, yet I have seen—we all have seen—patients who have been actually operated upon for the cure of hemorrhoids when the cause of their distress was a rectal carcinoma, perhaps not at the time of operation within finger reach.

A woman with rectal hemorrhages from a papillomatous colitis, which later necessitated a complete colectomy, had been operated upon for hemorrhoids, which in truth may have been present, and the actual source of the bleeding was not discovered until it became evident that no relief had followed the clamp and cautery.

In disease of the urinary system the matter of thorough and what may be termed "special" examination is of great moment. In a case of sudden hematuria in an individual of middle age the suspicion of malignancy is to be confirmed or eliminated, not as a last but as a first step.

I will assume that most practitioners are able to do their own ordinary microscopy. Also, that they know how to employ the two-glass test, and by catheterization and lavage to decide whether the probable bleeding is from the kidney, the bladder or the urethra—in the male or the female.

A more accurate diagnosis may not be possible, however, without what are called "special" examinations—with the aid of the cystoscope, the x-ray, the ureter catheter. And here permit me to mention a point which I have emphasized on other occasions. The x-ray should take precedence of what may be called the operative procedures of cystoscopy and ureteral catheterization because it is less liable to do harm. In the male, and the aged male in particular, the mere passing of an instrument for the first time may have consequences of a serious

nature due to traumatism and infection—possibilities which can never be absolutely ignored. I have seen dangerous hemorrhage follow cystoscopy in a man with prostatic disease and so-called "hemorrhoids of the bladder," while fatal "catheter chill" is not unknown even in these days of improved urinary antisepsis. If unfortunately the x-ray examination must be repeated, at any rate we shall have avoided one unnecessary cystoscopy. But in any case, these examinations should be made as soon as possible after the suspicious hemorrhage and there must be no placebo or "expectant treatment." If there is indeed a carcinoma, temporary drug relief from symptoms will be the worst thing that could happen, for it will quiet the patient and meantime permit further development of the tumor.

As every progressive practitioner knows, a patient in whom cancer is even dimly suspected should be seen by a surgeon. There can be little loss of prestige and there will surely be great relief of mind on the part of the physician, if even thus early, he will divide his responsibility. Perhaps too often he shares the feeling of his patient that the surgeon's motto is "When in doubt, operate"; yet this motto is on the whole a very safe one when dealing with cancer—always provided that no legitimate means of diagnosis has been omitted.

But the experienced surgeon appreciates the actual risk probably better than any one else, for upon him falls heaviest the blame for an untoward result. And the punishment for failure is far greater in proportion than any reward of success, for when the surgeon unfortunately loses his patient he too often loses the confidence of what may be called the entire "Circle" about that patient and also the physician who referred the case. And a so-called operative recovery with the disease unrelieved is like the mistake of an architect—always in evidence as a reproach to his poor judgment or lack of skill.

In advanced cancer particularly, the mature surgeon has learned to shun operative pyrotechnics, preferring always to relieve the distress rather than to risk all in a desperate attempt at radical cure.

Take, for example, the operative treatment for cancer which closes up the pyloric end or outlet of the stomach. The work naturally divides itself into two portions. First, the formation of a new opening between stomach and intestines—the gastro-enterostomy—which short circuits the diseased parts, permitting the food to pass unobstructed into the intestines, and second, the extirpation of the cancerous part of the stomach. When we are fortunate enough to deal with an early case and a small tumor, both these operations can safely be performed at one sitting. But when infection and ulceration are added to the cancer and there is a large inflammatory mass around the pylorus, the patient weak from starvation, it is not the cancer poisons which are killing him, but the lack of nutrition. Now, after a short and comparatively safe operation, the patient can eat again, and in two or three weeks he will be a good "safe risk" for further surgery. When the abdomen is opened for the second time the tumor will have diminished wonderfully in size and can be removed with infinitely greater ease and safety than would have been possible at first.

This two-stage method has given me great satisfaction and I am morally sure that I have saved patients who would have died under the more brilliant single stage procedure.

What has just been said of dangerous and unpromising operations upon patients who are in any event doomed, does not mean that half-hearted work should be done when there is a chance for radical cure—even though life is thus put in great jeopardy. Take the latest field to be conquered in thoracic surgery, in which the first battle was won by Franz Torek of New York, on March 14, 1913, when he successfully removed a cancer of the esophagus through the chest wall. This most formidable piece of work would not have been justified had there been secondary deposits in other parts of the body. Relief, not an attempt at cure, would then have been the proper aim of the surgeon. But when he was able to remove the entire growth and rid the patient once and for all of that cancer, the extent of the operation and even its great mutilation were not worth considering.

Before this audience it is hardly necessary to emphasize this aspect of the cancer fight. You surely know, for example, the remarkable improvement which has followed the adoption of the present operation for carcinoma of the breast. How hopeful is the outlook even in most malignant forms of the disease when a complete operation is performed early.

As an instance I may briefly mention the case of Mrs. M., a woman 38 years old, who found a nodule the size of a large bean in the outer upper part of her left mammary gland. The important point was that she was sure that there had been nothing there only a few weeks before. Her physician referred her to me, and in general anesthesia the little tumor was widely excised and at once examined. It proved to be carcinoma. So without interrupting narcosis the entire breast was amputated, with its underlying muscles and the glands in the armpit—an operation which twenty years ago would have seemed out of all proportion to a focus of such apparently insignificant size. But this patient, and many others treated in the same manner, has been permanently relieved of a condition surely fatal if left to itself.

It is generally conceded by the medical profession that cancer begins, through infection or otherwise, in one small part of the body; but there comes a time, sooner or later, when it invades other tissues or organs, either in the immediate neighborhood of the parent tumor, or even at a distance, until finally the condition of

carcinosis or generalized cancer is established. The usual cause of death is the poisoning of the system by the toxins absorbed from the growths. Surgeons are well agreed that if a primary or parent cancer is totally removed by an operation it will not recur, though of course we know of nothing to prevent the appearance of an entirely new tumor. Now all cancers are malignant and progressive, though some grow much faster than others, so it is perfectly plain that the sooner after its appearance a cancer is extirpated the better will be the chance of permanent cure.

In view of the still deplorable procrastination which we note in most of these cases, a delay which more than the disease itself brings reproach upon the surgeon, where it does not belong, instead of on the patient, where it does, it occurred to me to go over the cases in my private practice to learn how much time elapsed after the first suspicion of malignancy before surgical aid was sought.

Realizing that public information—I will not say education—has become much more general in recent years, I examined the last 2000 histories in my case books and learned some interesting things.

1. There were 86 cases of malignancy, or 4.3%. At this point I became interested to learn the percentage of malignancy among the class of individuals who would naturally drift to the public wards of hospitals. So I made investigations with the kind permission of the superintendents of five large hospitals in New York. In each institution the diagnosis on discharge was made the object of inquiry, and I learned that in 2000 consecutive surgical ward patients there had been:—

In Mount Sinai Hospital, 84 cases of malignancy, or 4.2%.

In St. Luke's Hospital, 82 cases of malignancy, or 4.1%.

In Presbyterian Hospital (in 2345 cases in 1912 including 400 private patients), 127 cases of malignancy, or 5.4%.

(And in the last 1084 cases in the new indexing system, there were 121 cases of malignancy, or 11.16%.)

In Roosevelt Hospital (2000 patients), 129 cases of malignancy, or 6.45%.

In New York Hospital (2000 patients), 34 cases of malignancy, or 1.7%.

An astonishingly small percentage, perhaps accounted for by the fact that this hospital has a very large ambulance service—so that many of the 2000 cases were of insignificant injuries.

Now, counting all these groups of approximately 2000 cases together we have in 12,345 patients, 542 instances of cancer, or 4.39%, which means that one in every 22 surgical patients had cancer.

2. Of my own 86 patients, 65 had never been operated upon and may be called new cases. The others came on account of secondary or recurrent disease and need not here be considered.

3. Of the 65, 10 were sarcomata, 55 carcinomata.

4. Of the 65, 35 were in men, 30 in women.

But the most interesting fact from the surgeon's viewpoint was the answer to my original inquiry, concerning the promptness or tardiness of the surgical consultation.

5. I found that after the first discovery of a tumor, or after the first suspicious symptoms, the men had waited on the average 12.2 months before consulting the surgeon, the women 11.9 months, a difference of but nine days. Evidently the sexes are after all pretty evenly divided in regard to wisdom, or rather the lack of it, for no person of good sense could describe as wise the delay of a year in a matter so vitally important.

Now we know that very few persons discover or suspect the presence of cancer until the symptoms are very pronounced, or until there is a tumor of considerable size; also that such a tumor, with or without symptoms, has probably been in existence for say six months before it was discovered. So that we may assume that cancer patients do not come to the operating table until at least a year and a half after the onset of the malignant disease.

Precious time thrown away; great dangerous operations to be undergone instead of minor ones.

Surely with such a handicap the wonder is that science and skill have been able to make the steady headway which has been shown in the last twenty years of surgery.

Whatever may be the discoveries of the future, there is no excuse for failure to grasp at once the hope held out by the present.

CORYNEBACTERIUM HODGKINI IN LYMPHATIC LEUKEMIA AND HODGKIN'S DISEASE.

BY ALBERT E. STEELE, M.D., BOSTON,

Assistant in Clinical Bacteriology, Massachusetts General Hospitals Instructor in Bacteriology, Harvard Medical School.

From the Pathological Laboratory, Massachusetts General Hospital, Dr. James Homer Wright, Director.

NEGRI and Mieremet[1] recently announced the cultivation of a bacillus from two cases of "Malignant Granuloma." They cultivated this organism from the lymph nodes and spleen of the first case (post-mortem) and from the cervical lymph nodes of the second case. The bacillus was also found in the sediment of the spleen pulp which had been treated with antiformine as well as in stained sections of the spleen.

They made extensive cultural and animal experiments and think that this bacillus may be the cause of the disease.

Bunting and Yates[2] observed the same bacillus in cultures of the lymph nodes from seven cases of Hodgkin's Disease; they designate it "Corynebacterium Hodgkini" and claim to have produced in a monkey "progressive enlargement of a single group of lymph nodes which at the time of writing show histological changes identical with those seen in the lymph nodes of human beings where the disease is of the same duration."

Billings and Rosenow[3] isolated the bacillus from the lymph nodes of 12 cases of Hodgkin's disease; they have suggested that vaccines may be of value in the treatment of the disease.

Cultures were recently taken from the lymph nodes of two cases at the Massachusetts General Hospital. The first case was one of lymphatic leukemia and the second case, one of Hodgkin's disease. The bacilli isolated from both of these cases were morphologically and culturally identical. They were also apparently identical with the bacilli described by the authors above mentioned.

CASE 1 was a boy of twelve years who entered the east medical service of the Massachusetts General Hospital, in charge of Dr. D. L. Edsall, on Nov. 1, 1913.

When three years of age, he had had measles; but was otherwise well until two years ago. At that time some of the teeth in his left lower jaw were filled; this was followed by toothache and swelling of the lymph nodes. The teeth were then removed, the swelling and pain disappeared and he was well until three weeks before his entrance to the hospital.

He then noticed a painless swelling in both sides of his neck; and, a week later, an enlargement in both axillae; he also had pain in his left upper abdomen.

He attended school but was sent home by the school physician. He was then seen in consultation by Dr. H. F. Vickery, who advised his removal to the Massachusetts General Hospital.

On entrance, his physical examination was negative except for the enlarged lymph nodes, tonsils and spleen. Below both ears was a mass of glands about the size of an egg, with numerous smaller, firm, discreet glands lower in the neck; palpable glands were present in both axillae and groins. None of the glands were tender. Both tonsils were enlarged and their crypts contained pus. The spleen was enlarged to percussion and easily felt 3 cm. below the costal margin.

Blood examination at this time showed 5,286,000 red blood cells and 65,800 white blood cells per cubic millimeter. There was 75% hemoglobin. The white blood cells were 80% lymphocytes and 20% polynuclears. Blood platelets were rare.

On November 3, an x-ray showed a mediastinal mass which was thought to be enlarged glands.

On November 5, the patient's tonsils and adenoids were removed to relieve difficulty in breathing and to remove the pus foci.

On November 6, the white blood count was 220,000; 99% lymphocytes and 1% polynuclears.

On November 7, the white count was only 1,800; 55% polynuclears and 42% lymphocytes. Coincident with this drop in the white blood cell count, there was a marked diminution in the size of the spleen which could not be felt below the costal margin and a diminution in the size of the lymph nodes from the size of an egg to that of a bean. The blood platelets at this time were estimated as being normal in number.

About November 20, the lymph nodes again increased in size, the spleen became palpable and the white blood count was raised to 9,000. The differential count remained practically the same, however, until November 28, when the white cells were 236,000 per cu. mm., 80% of which were lymphocytes and 20% polynuclears. The spleen could now be felt 5 cm. below the costal margin.

On November 28, one of the right inguinal lymph nodes was removed, ground in a sterile mortar and planted on various media.

Eleven tubes were inoculated; seven of these showed a growth of the bacilli described below, after five days' incubation.

A vaccine was prepared as soon as possible; 50 million bacilli were inoculated on December 6 and 50 million on December 10.

The patient's condition did not improve; he became gradually weaker; the spleen, liver and lymph nodes increased in size; the white cell count rose to 298,000—99% lymphocytes and 1% polynuclears—and the platelets were diminished.

He died of weakness and of adenoid hemorrhage on December 12.

CASE 2 was a woman, 30 years of age. She had typhoid fever seven years ago but with this exception has always been well.

The present illness dates from March, 1913, when she noticed a small glandular swelling in the left side of her neck. A few days after she observed this swelling, she noticed other glands in her left axilla and in her right neck.

For three weeks before entrance, she noticed that these glands were growing rapidly larger; that she was short of breath and weak. For these reasons she was admitted to the east surgical service of the Massachusetts General Hospital on Nov. 26, 1913.

The patient was a well-developed, rather emaciated woman. She had a mass of glands, the size of a lemon in her left neck; a mass of the same size in her right neck.

There were numerous discreet glands above the right clavicle. And a glandular mass about the size of an orange in the right axilla. Enlarged glands were also present in her left axilla and in both groins. Her physical examination was otherwise negative. Her blood examinations were as follows:

November 26, white blood cell count 8,400.

December 1, red blood cell count 3,552,000; white blood cell count 7,680.

A stained specimen showed the following: Polymorphonuclears, 86%; lymphocytes, large, 7%; lymphocytes, small, 3%; lymphocytes, transitional, 3%; unidentified, 1%.

Glands were removed from the patient on December 6 for pathological examination and on December 10 for culture.

A diphtheroid bacillus, similar to the one observed in the preceding case, was obtained in pure culture in four tubes; six others were inoculated but showed growth.

The patient was discharged from the hospital shortly after the cultures were taken and she has not returned as advised. Her subsequent history is not known at present.

BIOLOGY OF THE ORGANISM.

The bacteria cultivated are markedly pleomorphic. Most of the organisms resemble forms of the diphtheria bacillus; but some are short and coccoid. I have not observed any definite branching forms.

Some take the stain uniformly, others show a granular character while still others take the stain more deeply at the ends. They stain by Gram's method, are not acid-fast and are resistant to antiformin.

They grow at first slowly, growth being first visible after five days' incubation. Transplants grow well on most of the ordinary culture media, but best in media rich in body albumen.

On agar and blood serum, the lemon yellow fluorescence observed by Negri and Mieremet, is particularly noticeable. On potato, the growth appears as small isolated lemon-yellow colonies. The growth in bouillon or ascites bouillon, is at first in adherent masses although later the bouillon is somewhat clouded. It grows as isolated yellow colonies in gelatine, without liquefaction. It does not produce gas in glucose or lactose.

SUMMARY.

A diphtheroid bacillus, similar in its morphological and cultural characteristics to the organism described by Negri and Mieremet, Bunting and Yates, and Billings and Rosenow has been cultivated from the lymph nodes of a case of lymphatic leukemia, and one of Hodgkin's disease.

Its relationship to these diseases has not been definitely determined, although further studies on this subject are in progress.

THE CONDITION OF THE VASO-MOTOR CENTER IN PNEUMONIA.

BY W. T. PORTER, M.D., BOSTON,

AND

L. H. NEWBURGH, M.D., BOSTON.

From the Laboratory of Comparative Physiology, Harvard Medical School.

SINCE 1889[1], it has been generally believed that the vaso-motor centre is exhausted in "pneumonia." The most important carrier of impulses to this centre is the depressor nerve. The average fall of blood pressure, produced by the stimulation of the depressor nerve in normal animals is a measure of the normal state of the vaso-motor apparatus. The sciatic nerve also contains important fibers afferent to the vaso-motor centre and the rise of blood pressure produced on stimulating the central end of the sciatic nerve is also an index of the condition of the vaso-motor centre.

The present investigation consists in the production of lobar pneumonia (acute pneumonitis) in cats and in the comparison of the changes in blood pressure obtained by stimulating the depressor and the sciatic nerve in animals near death from this disease with the changes obtained by the stimulation of these nerves in normal animals.

We have produced pneumonia in cats* by blowing into the trachea cultures of pneumococcus mixed with carborundum powder.

The details will be found in a paper to be published in the *American Journal of Physiology*.

A few hours before death the stimulation of the depressor fibers in the vagus nerve gave a fall of blood pressure equal to the average normal fall, and stimulation of the pressor fibers in the sciatic nerve gave a normal rise of blood pressure.

Following is a typical protocol for a depressor experiment:—

Experiment Dec. 16, 1913. At 10 a. m. a cat weighing 1750 grams was etherized and ten cubic centimeters of a twenty-four hour culture of pneumococcus, grown in glucose bouillon, was injected through the glottis and the trachea into a bronchus. At 4 p. m. the rectal temperature was 38° C., and the cat was apparently well.

Dec. 17, 10 a. m., temperature was 38° C., and the cat seemed well. Under ether 10 cubic centimeters of a twenty-four hour glucose bouillon culture of the pneumococcus, plus one gram powdered carborundum, was injected into a bronchus. At 4.30 p. m. the temperature was 40° C.; the cat was listless and moderately ill.

Dec. 18, 10 a. m. Temperature, 40°C., condition about the same, breathing labored and rapid. 4.30 p. m., temperature 39° C. Animal seems a little better.

Dec. 19, 9 a. m. Temperature, 39° C. 4.30 p. m., temperature 39° C., animal weak and ill. Five cubic centimeters of a twenty-four hour glucose bouillon culture pneumococcus injected through the trachea.

Dec. 20, 9.15 a. m. Temperature 38° C., condition unchanged. Under ether the left carotid artery was connected to a membrane manometer, both vagi were cut and the central end of the left vagus was stimulated with induction currents perceptible when the electrodes were placed on the operator's tongue. The blood pressure fell from 100 mm. Hg. to 65 mm. The absolute fall was 35 mm., and the percentile fall 35%. At 5 p. m. the cat was killed.

Autopsy: The lower lobes and the lower halves of the middle lobes on both sides were voluminous, firm, leathery, dull red-gray in color. They sank in water. On section the surface was gray-red, granular, dry. The remainder of the lung was pale, soft, crepitant and floated in water.

* So far as we are aware this is the first time acute lobar pneumonitis has been produced in cats.

In the experiment of Jan. 2, 1914, in a cat with complete consolidation of the right lower lobe of the lung the temperature was 41 degrees C., the stimulation of the central end of the left sciatic nerve caused the blood pressure to rise from 55 m.m. to 125 m.m. Hg; an absolute rise of 70 m.m.

The vaso-motor reflexes obtained from the depressor and the sciatic nerve were equal to the reflex in normal animals.

The evidence is conclusive that, in animals near death from pneumonia, the vaso-motor apparatus is not measurably impaired.

A STUDY OF CANCER.

BY SEELYE W. LITTLE, M.D., ROCHESTER, N. Y.

(*Continued from page* 80.)

To revert again to the skin. In considering wounds we must remember several facts in this connection. The epidermis is itself protective; it is composed of one of the few kinds of cells which can reproduce, and most important of all it is of all tissues the one that keeps alive physiologically the longest. Witness the growth of hair and nails after death. Now put this with that other well known fact about cancer, its chief occurrence after the period of growth and development and largely in organs which have served their purpose, such as breast and uterus, and we can see why skin cancer is rarer than we should expect with wounds alone in view. For skin can repair itself and is physiologically active generally until death of the organism and even after.

6. The stomach. The commonest single seat of cancer. Next to the skin it is the worst treated organ in the body and increasingly so as civilization advances. It is quite likely that with alcohol, spices, indigestible food, hot and cold food and the like, we cause minute wounds of the gastric mucous membrane daily, and especially do we injure the narrow alternately dilating and contracting channel, the pylorus, through which all these must pass.

Now for two conceivable ways in which a wound may derange a cell or a group of cells so as to start them towards a riotous and destructive growth. A group of epithelial cells is injured. At once a process of repair begins. If the cells are not too badly injured they can again become perfect and resume their functions. If so badly damaged that complete repair is impossible, they may imperfectly resume function. If more damaged, they may live, but so crippled as to be unable to do their work at all, but still alive and ready for mischief. Or, more probably, in the process of repair and the manufacture of scar tissue some perfectly good uninjured neighboring cells are so shut in and enclosed as to be unable to functionate in the normal way; but they, too, are very much alive. In fact, not functionating but lying dormant, as it were, they are not physiologically dying at all after a lapse of several years when their hard-working fellows are dying. Now comes the relative failure of their patron ductless gland. And by the way, this failure may be only relative to these shut-in cells. That is, the failure may be just in the right proportion for all the other physiologically failing cells, but not for these idlers who have not worked for years. Their accustomed fare is shut off; there is still plenty, but not "what they have been accustomed to." They deteriorate, but they thrive over their fellows because they are physiologically younger. At a certain point in deterioration they are at the stage where the elementary functions return and they can reproduce their kind, which is now a poor imitation of their once highly specialized selves, and they do reproduce.

Again, the same possible degeneration may result purely as an effect of repeated slight injury over a long time, the injured cells then falling far behind their fellows physiologically from overwork. In this case we must assume that these cells are physiologically much older than their fellows, and though the ductless gland is failing *pari passu* with all other body cells, yet for these overworked cells there is actually an over secretion of the patron ductless gland with resultant actual stimulation of the deteriorated cells to their youthful function of reproduction.

Of these two possibilities, the former seems much more probable.

If all this is true, the question at once arises, why is not cancer almost universal after middle life? My explanation of this is at the base of all that follows as to cause and treatment. And incidentally it also answers why is not childhood, the time of bumps and bruises, also the time of cancer?

It is a truism that as soon as a man ceases growing and developing he begins dying. If, within bounds, you injure a growing cell, it goes right on growing again, perhaps even better than before. In fact it is apt to be a hardier cell for having fought against and conquered enemies. The gardener prunes unmercifully to get a hardier and more perfect growth. But after growth has ceased or after the limit of growth has been attained, pruning not only does no good, but it destroys what has already been accomplished. Now injury to a child's cells within reason does no particular harm, for it is the child's main object in life to grow and to perfect what is already there. We all know clinically how quickly children rebound after a severe illness. But after growth has ceased, cell injury of even slight character may easily be a serious matter because irreparable.

Facts learned in recent years have a very important bearing on this matter. We know now that certain organs in the body, formerly of no known use, are really and literally of vital importance, for they have to do with growth, and without them growth is imperfect or indeed impossible. Such organs are the pineal body, the pituitary body, the thymus, the thyroid, the adrenals, the generative organs, etc.

The next important link is the fact that all organs do not die physiologically at the same time. The thymus and the thyroid, for example. Next comes another well known fact, *i.e.* organs that theoretically and naturally ought to die at the same time do not do so. A man may have hard arteries at forty instead of at seventy, with the brain still at the forty-year stage. This in general seems to me to explain very many of the diseases due to civilized life as opposed to natural life. And I believe it explains cancer.

That is, ductless glands and the cells where cancer starts are not in physiological harmony. This might happen in many ways; perhaps as already explained.

This theory of cancer is at variance with no known facts about cancer and certainly explains very satisfactorily most of those facts. Even if, as seems improbable, cancer should be proven of parasitic origin, it is easily possible that the parasite might work not directly to cause cell growth, but indirectly by weakening either the cells or the ductless glands involved, or both. If cancer is proven to be of chemical origin, the same holds true.

This theory explains the general incidence of cancer at and after middle life, its increasing virulence the younger the patient, its attacking only highly specialized cells, its etiological relation, frequent if not invariable, to trauma, its highly probable non-existent contagiousness except auto-contagiousness (what we call recurrence), its rare though possible "spontaneous" cure, the only known positive cure, early exterpation, its cachexia (due to the simpler cells getting the bulk of the food, the absorption of waste products from the same cells, and most important of all, the necessary faulty metabolism of the whole system), the known incidence of the disease proportionately in the various organs, as shown in table 3, the increasing incidence of cancer as the complexity of civilization increases, and many other facts of lesser importance. But the thing can occur only by proper combination of injury, specialized cells shut in for a long time and relative failure of the essential ductless gland for the given case.

Before discussing possible curative measures on the basis of this theory and giving the clinical results of some of these possibilities already tried, another matter of the highest importance should be considered, because it certainly has a bearing on the subject. I refer to lime metabolism and sugar metabolism, their relation to the ductless glands, to various disease processes and to each other. This matter has in recent years received much attention and many important facts have been discovered. Our idea of one disease at least, diabetes, has thereby been revolutionized and the ductless glands have been found to have an unexpectedly large part in this metabolism. Because of the large clinical experience of diabetes sugar metabolism has been the more studied and much more is known of it than of lime metabolism. It is now known positively, for example, that, besides diabetes, such widely differing clinical entities as the following have an important relation to sugar metabolism: cretinism, acromegaly, giantism, Graves' disease, Addison's disease, myxedema, and cancer, to say nothing of eczema, psoriasis, rheumatism gout, and a host of minor ailments. It is astonishing to find that the classical puncture at the base of the brain fails to produce glycosuria if the suprarenals are lacking, that a hypodermic dose of a few milligrams of adrenalin always produces in normals a temporary glycosuria which may not reappear at subsequent injections, that if the thyroid is removed, adrenalin fails to produce glycosuria, but that, on the other hand, if the parathyroids are removed the glycosuria effect of an adrenalin injection is greatly increased; that in some diseases it is almost impossible to produce glycosuria, that in some diseases there is a craving for sugar which, though satisfied, does not produce glycosuria; that in others there is no craving for sweets at all; that in some there is excess of sugar in the blood without glycosuria. It is very suggestive to find, for example, that diabetes and cancer occur in the same individual at the same time with the greatest rarity, that psoriasis is a very common predecessor of cancer, and that in cancer there is often, perhaps always, a hyperglycemia, though very rarely a glycosuria. It is interesting to know that in giantism, for example, where calcium metabolism must be enormous, and in acromegaly, where the same is true, diabetes is common at certain stages, but on the contrary when the active disease has ceased and there is actually a hypo instead of a hyper pituitarism, the sugar tolerance is very high and diabetes is almost an impossibility. Again, in the disorders of pregnancy, it is suggestive that sugar and lime seem to have intimate relations. Teeth often decay at this time, glycosuria is not uncommon, the administration of lime certainly has some influence on the prevention or control of eclampsia, and incidentally remember that in pregnancy both the thyroid and the pituitary are commonly hypertrophied. In this connection recall also the not uncommon myxedematous condition of hands, feet and face without kidney lesions and without true edema, and recall how after labor this enlargement of face and extremities usually subsides.

Such are some of the remarkable facts with reference to calcium and sugar metabolism. They are introduced merely to show how important this subject is and to show that in all probability there is certainly a derangement of sugar

metabolism in cancer, that this is an important element in cancer and that it is an element generally, if not always, associated with disordered function of one or more ductless glands; that calcium metabolism and sugar metabolism are intimately related and doubtless so in cancer where we know positively the sugar metabolism is.

Granted that this general theory of cancer is at least a reasonable one and points in the right direction, the question at once arises, "Are we any nearer a cure for cancer?" I think we are decidedly. In medicine theory is of ultimate use only as it helps restore sick people to health. The man with cancer cares not at all about theories, systems, serums, germs, or anything else unless he can recover. Therefore some of us have been treating cancer on the basis of the theory of cause already outlined. We had first to become more definite. We had to decide in a given case which ductless gland or glands were at fault and whether it was a fault of hyper or hypo secretion or a secretion correct in amount but faulty in composition.

For obvious reasons only inoperable cases were selected, and I will say at the outset of the clinical discussion that very astounding results were apparent in every case in a few weeks, so much so that the three or four medical men who were interested were sure that, whatever the ultimate result, we were on the track of something of the first importance in medicine.

The pituitary gland was first considered because of the known fact of its great importance normally in the matter of growth. We proceeded on the theory that this gland in cancer was hypersecreting at a time of life when it should be failing along with general bodily failure, and that certain cells long idle, because shut in by scar tissue, as already described, were not in the same degree of physiological dying as their fellows and therefore were activated by the hyperpituitarism. But these idle cells could not respond as they should to such stimulation in a normal fashion, being shut in as it were. Therefore we presumed they did only what they could. Now a cell can really do only a few things in the last analysis: it can eat, pass off waste matter, move, grow, secrete something, and finally, most important of all and really most essential for all life, it can reproduce its kind. Specialized cells, certainly in their old age, do not reproduce their kind; that function they have delegated, in humans, to other specialized cells. But if a specialized cell is prevented from doing its special work for a long time, it loses that power. Furthermore, if it is alive and well fed it will certainly do something. We assumed that such cells are the focus for cancer. That is, they are healthy but physiologically deteriorated cells which are comparatively young, and which receive an extra stimulus from the hyperpituitarism. They, therefore, do the only thing left for them to do. They reproduce their kind, atypical to be sure, but characteristic. And being, relatively to the other body cells, young, they are active out of all proportion to other cells. In other words, we have a cancer.

On this assumption, the rational thing would seem to be to remove some of the pituitary body. But for a patient far advanced in cancer, such a procedure was negatived. The risk was too great. It then occurred to me that the pituitary gland is an organ which certainly has two very remarkable and apparently widely separated functions: it regulates growth and it helps regulate sugar metabolism. I decided to make it work overtime at the sugar metabolism, hoping that so much of its energy would thus be occupied that it could not devote much to its growth function. I was encouraged to this opinion by the known fact that cancer and diabetes are extremely rare in the same patient. Therefore I decided to feed the first patient with inoperable cancer I had with large amounts of sugar. The result was so extraordinary that it was with difficulty I could think of anything else, for this patient apparently entirely recovered within two months. Fortunately or unfortunately, the fact that I had no scientific proof that the case really was cancer prevented me from at once rushing into print. Clinically, however, the woman was dying from uterine cancer. Her case is Case 1 described later. But I did enlist the help of some of my fellows and told them my theory and the result. We then tried the thing out with four other patients, one cancer of stomach, one cancer of esophagus, one cancer of skin and one cancer of tongue. There is no scientific doubt at all as to the nature of these cases. The stomach case died in the usual way, the esophagus case died with a metastasis in lung, the tongue case and skin case are under treatment.

All four cases promptly showed three remarkable results. All had a feeling of well-being, three even gained in weight, all were relieved of pain and in all the growth diminished in size. This is surely enough to show that something new was being done and was tremendously encouraging. The results in the esophagus case and in the stomach case only served to start fresh studies which at once opened wide fields. In passing it seems probable that at least one new disease entity has been recognized and many otherwise puzzling cases have been more or less cleared up.

At this point the writer made a careful tabulation of various known facts with reference to the ductless glands. These tabulations appear elsewhere. As a result, the theory was changed. It seemed highly probable that in each case of cancer, depending on its embryological location, a special ductless gland was chiefly involved. For example, the pituitary body is embryologically ectoderm and the stomach is endoderm, and it seemed more likely that if any ductless gland were at fault in cancer of the stomach it would be a gland of endodermic origin, *i.e.* thymus, thyroid, parathyroid, islands of Langerhans or the gastric and intestinal mucosa.

Again, it was enlightening to find that one or more of the ductless glands derived from each of the three germ layers had something to do with sugar metabolism. (See Table 6.) It was still further enlightening to find that always, so far as we could determine, in cancer there is hyperglycemia, but, as already stated, rarely glycosuria. And it seemed almost impossible to produce an alimentary glycosuria.

Another of the tables shows how hyperglycemia may be produced. (Table 7.) It will be seen that in the case of some of the ductless glands, as the suprarenals, for example, hyperaction produces an excess of sugar in the blood, while in the cases of others, the pituitary for example, hypo action does the same thing.

Taking all things into consideration it was believed finally that it must be a case of hypo action of one or more of the ductless glands that was the ultimate causative factor in cancer, as explained earlier in this discussion; either this or a disordered action,—what Cushing in speaking of the pituitary body calls dyspituitarism. The explanation on this hypothesis would be again that the disordered action would affect most strongly the physiologically younger cells, the shut-in idle cells before mentioned.

With this idea, I began on the skin case, which under the sugar treatment had improved to a certain point and then the growth began vigorously in a new spot adjoining the old growth. In considering what gland was at fault, we find on consulting Table 1 that skin is of ectodermic origin. Table 2 shows that the following ductless glands are also of ectodermic origin: A part of the suprarenal, the pituitary, the carotid bodies, the pineal body and possibly the coccygeal body. The last three were ruled out because we knew little about them, but that little does not bear on the present subject. The suprarenal we rule out because hypo adrenalism does not result in hyperglycemia and does result in a well known disease entity—Addison's disease. There remains the pituitary. If the pituitary is at fault in such a case we can rule out hyperpituitarism for its results we know—acromegaly, or in the young, giantism. Therefore we are brought to the theory of hypopituitarism.

The suprarenal was strongly considered at first on the ground that if one omits the actual growth, many of the symptoms of cancer and of Addison's disease are alike: weakness, digestive disturbances, wasting, cachexia, etc. In fact we administered adrenalin, but without much effect one way or another. Again, as a side issue, it may be stated that for reasons not necessary to discuss in this place, adrenalin medication is disappointing, but we have under consideration some interesting possibilities in this connection. Also there seems a fairly definite symptom complex, the exact antithesis of Addison's disease, of which the writer has complete records of two cases. There are certainly many such cases.

So finally on Aug. 26 we began the administration of pituitrin, meanwhile keeping up the sugar administration until Oct. 1, when it was discontinued for reasons to be given presently.

On Oct. 1 there was found to be a very remarkable change in the growth We had not seen the patient since the pituitrin had been started but now we found the growth shrunken to a shadow of its former size, and the whole ulcerated surface healing. (Full details of this case will be given later with the other cases.) But we found the patient had been losing weight and strength while his cancer was disappearing. Several explanations of this were considered. We thought it might be due to too much sugar now that we were furnishing extra pituitrin to the patient, or that it might be due to toxins absorbed from the disappearing growth. At all events we stopped the sugar, urged a generous diet otherwise and gave strychnine. The urine at this time showed the characteristic increase due to the pituitrin. On analysis we found the urine to be of sp. gr. 1.012, acid, possibly a very faint trace of albumin, no sugar.

The tongue case (No. 6), doing badly after the usual initial gain, was next reconsidered.

On consulting Table 1 we find the tongue to be of endodermic origin. Table 2 shows the ductless glands of endodermic origin to be the thymus, the thyroid, the islands of Langerhans, the gastric and intestinal mucosa.

The thymus was ruled out as it is generally negligible after puberty. The thyroid was ruled out (although it was tried for a short time) because we knew the usual effects of hyper- and hypothyroidism in Graves' disease, myxedema and cretinism. The islands of Langerhans were ruled out, at least so far as hyper function is concerned for reasons already given. Hypo-function we know is the usually accepted cause of diabetes. There is very strong ground, however, for seriously considering relative hypofunction of the islands of Langerhans as one of the factors in producing cancer of endodermic tissues. If there is such hypo-function we expect diabetes; but suppose in a given individual there exists a nest of our assumed "idler" cells. When as the first result of hyposecretion of the islands of Langerhans an excess of sugar appears in the blood, that is exactly what suits these physiologically younger and more active cells which from disuse have lost their specialized functions and have deteriorated. They eagerly seize upon this extra food and thrive upon it; if at the proper stage of retrogressive development they multiply and the cancer is started; as the failure in the islands of Langerhans increases and the amount of sugar in the blood thereby increases, the cancer naturally grows, taking all the sugar that can be furnished because the increase is gradual. Therefore a person at or after middle life who has hypo-secretion of the islands of Langerhans will have diabetes or cancer, depending upon whether or not he has the other factors of cancer present. It is curious to note that many more children have diabetes than have cancer, but that very many

more people at or after middle life have cancer than have diabetes. The reason is obvious if our theory is correct.

Therefore hypo-secretion of the islands of Langerhans must be seriously considered in the case of endodermic cancer. A reliable preparation from these organs has not yet been obtained to use in any cancer case as yet.

(To be continued.)

Clinical Department.

MEASLES: ITS RELATION TO ORAL CONDITIONS; WITH A CLINICAL REPORT OF SIX CASES.*

BY H. C. HOYE, D.M.D., BELMONT, MASS.,

Assistant at St. Vincent's Orphan Asylum Clinic, Boston, Massachusetts.

MEASLES is an acute, contagious, febrile disorder, characterized by catarrhal symptoms affecting the upper respiratory tract, and an eruption of dusky-red, slightly elevated macules. It is the most contagious of the various exanthematous affections and it is almost impossible to prevent its spread in an institution or household. Susceptibility to measles is practically universal. It may attack anyone who is not already immunized by a previous attack.

The eruption of measles may be seen on the mucous membrane of the mouth previous to its appearance on the cutaneous surfaces. The eruption occurs usually on the second day. Flindt[1] in 1880 describes the exanthem of measles as follows: "The eruption consists of round or somewhat irregularly shaped, light red spots, rather indistinctly circumscribed, and only just raised above the mucous surface. The spots vary in size from a pinhead to a lentil, are in part isolated and in part collected into groups, quite irregular in shape, and in some places coalescent. At the centre of the small red spots, and giving them a peculiar appearance, are situated numbers of tiny, whitish, shiny, raised points, apparently vesicular in character and irregularly grouped according to the arrangement of the spots on which they lie. Similar spots can also be perceived on the mucous membrane of the cheeks."

One of the most remarkable and instructive epidemics of measles is that which visited the Faroe Islands in 1846. The island had been free from measles since 1781, a term of sixty-five years. The disease was introduced by a Danish cabinet maker, infected in Copenhagen. He communicated it to two friends. This gave rise to an epidemic which in a short time attacked 6000 people out of a population of 7782. Persons of all ages were stricken, the old inhabitants who had passed through an attack as children in 1781 alone escaped. Not one of the older inhabitants, who was exposed to this infection and was unprotected by previous attack, failed to acquire the disease.

The extreme contagiousness of measles, as shown in the preceding paragraph, is proof of its microparasitic origin. In 1892 Canon found in fourteen cases a bacillus, which he considered to be a specific causative agent. It could be grown on bouillon but on no other medium. Czajkowski[2] found a bacillus in the blood and mucous secretions of fifty cases of measles, which was apparently identical with that discovered by Canon. It grew, however, on various albuminous media. Josias[3] failed to find it in twenty-four cases; Barbier in twenty-one cases.

In 1900 Lesage[4] published the results of a study of two hundred cases. He found a delicate micrococcus, which grew best on gelose, took stains slowly, and was decolorized by Gram's method. The cultures bore resemblance to the Fraenkel's pneumococcus. Rabbits were inoculated with blood and nasal secretions in many cases, and measles was apparently reproduced in nearly all. The organism was found constantly in measles, but was absent in twenty-five cases of scarlet fever and in forty-five normal children.

More recently Weber[5] has detected bodies in the blood which he regards as protozoa. From the above divergent findings it is evident that further research is necessary before any of the organisms described can be accepted as the specific cause of measles.

It will be found convenient to discuss here the influence of institutional environment upon the mortality rate of measles. It is much more fatal in institutions than in the home and is often called "the scourge of children's institutions." Holt speaks of an epidemic in the Nursery and Child's Hospital in 1892 in New York in which there were 145 cases, with a death-rate of 35%.

In the St. Vincent's Orphan Asylum, Camden Street, Boston, the statistics of the cases of measles for the last six years, compiled by F. A. Keyes,[6] D.M.D., are as follows:—

1907-1908, 24; 1908-1909, 50; 1909-November, 1910, 40; November, 1910-April, 1911, 25; April, 1911-May, 1912, 0; May, 1912-May, 1913, 0; May, 1913-November, 1913, 6.

In April, 1913, a new child, infected with measles, spread the disease to six of the children. Examination of the mouths of these children showed the following conditions:—

CASE 1. Eight years old. Cavity in right inferior six-year molar; right inferior second temporary molar, badly decayed; left inferior first temporary molar, abscessed; right superior second temporary molar, decayed; mouth dirty; fetid breath; throat clear of tonsils; no adenoids present.

* Read at the monthly meeting of the Guild of St. Appolonia, Nov. 13, 1913.

CASE 2. Seven years old. Right superior second temporary molar, decayed to gum-line; right superior temporary cuspid, abscessed; cavity in left superior second temporary molar; left inferior second temporary molar, crown three-fourths gone; left inferior first temporary molar, decayed, with gums red and turgid; inferior right temporary molars, badly decayed; breath fetid; dirty mouth; tonsils present.

CASE 3. Five years old. Inferior right temporary molars, badly decayed; first temporary has an abscess discharging pus; left inferior first temporary molar, badly decayed; cavity in left inferior second temporary molar; superior right temporary molars, two proximal cavities; superior left first temporary molar, cavity in crown; tonsils enlarged; and adenoids present.

CASE 4. Five years old. Proximal cavities in the four anterior superior teeth;. inferior left first temporary molar, coronal cavity; teeth covered with green stain; gums red and turgid; tonsils enlarged. This is the child who brought the measles into the institution.

CASE 5. Three years old. Frenum enlarged; superior lateral incisors missing; on right superior central incisor gum has receded and is very red and turgid; on left superior temporary molars, roots are denuded; gums on lower, red and turgid; stomatitis present; this child was discharged from the hospital two weeks before this examination was made.

CASE 6. Eight years old. Superior right second temporary molar, abscessed; inferior left six-year molar, mesial cavity; inferior right temporary molars, decayed; gums red and turgid; mouth in six-year molar region very unhealthy; no tonsils.

It is an interesting fact that many of the children at the institution, whose mouths were in good condition, and who were exposed to the infection, were not attacked by the disease, although they had not been made immune by a previous attack.

From the investigations, as reported above, of research workers in all parts of the world, it is evident that measles is one of the most important of childhood diseases. Dentists should, by careful observation of the cases of measles occuring in their practise, be able to obtain interesting data in regard to the oral conditions found in these cases.

While we know that we have but few cases to report and that no logical conclusions can be drawn from so few, we trust we have aroused a little interest. In addition, we hope that other men, who have the opportunity, will observe the oral conditions found in cases of measles, occurring in their practise and report them.

Medical Progress.

FOURTH REPORT OF PROGRESS IN ORTHOPEDIC SURGERY.

BY ROBERT B. OSGOOD, M.D., F.A.C.S; ROBERT SOUTTER, M.D., F.A.C.S.; HERMANN BUCHOLZ, M.D., HARRY C. LOW, M.D.

TUBERCULOSIS.

Roentgen Ray Detection of Abscesses in Tuberculosis of the Spine. Roederer and Weil[1] for the last two years have been systematically examining with the Roentgen ray every child suspected of having tuberculosis of the spine. They have been surprised at the large proportion of cases in which shadows of abscesses were found about the vertebral focus. They call attention to the ease with which these abscesses can be detected by radioscopy before they induce any symptoms. These findings also emphasize the necessity for prolonged supervision, after an apparent healing of a vertebral process. They consider that with the present technic it is impossible to distinguish by radioscopy between incipient and florid abscesses or the cicatricial changes left after the healing of an abscess.

In America attention has been called to these facts and the ease with which abscesses in Pott's disease may be detected by radioscopic examination, by Compton Reily[2] of Baltimore.

Multiple Bony Tuberculous Lesions in Children. Calve[3] has made a valuable statistical study of the occurrence and prognosis of multiple tuberculous bony lesions in children. In various groups of cases collected by Dr. Glacys and from the records of the Hôpital Maritime at Berck the percentage of multiple lesions has varied from 9.4%, to 13%. In 1910 at Berck there were 85 cases of multiple foci among a total of 869 cases, making 9.8%. Of these 85 multiple cases, 27 were hip disease, 14 being double coxitis. In 9 hip and spine were involved. Thirty-four cases showing multiple lesions were apparently primary in the spine, and of these only five showed more than one vertebral focus, the more common association in this group being with the hip and knee. Tuberculous meningitis occurred about four times as frequently (5.9% to 1.45%) in the multiple cases as in the single. Among the 85 cases having multiple foci there were 8 deaths, 9.5%, while among the 784 cases having single foci there were 21 deaths, or 2.5%. The prognosis, therefore, would seem to be unquestionably more serious in the multiple than in the single cases.

Tuberculin. Delitala,[4] after a considerable experience with the use of tuberculin as a diagnostic agent, believes most strongly in the value of this focalizing reaction. He considers it of special usefulness in the early stages when diag-

nosis is most difficult, from both clinical and radiographic examination. He reports in detail 38 cases. His initial dose is 2-10 mg., his second 5-10, his third 1 mg., and his fourth 5 mg. He allows two days to elapse between each dose, and does not consider rises of temperature of two or three-tenths of a degree as a positive sign.

Treatment of Surgical Tuberculosis. Iselin[5] has treated 800 cases of surgical tuberculosis with the Roentgen rays. He believes that some of the cases in which even amputation had been considered, have been cured. In certain patients with multiple foci only those foci exposed to the rays were cured. There was frequently noted an increase of weight as well. He considers that the rays often do not have sufficient penetration to overcome the density of the bone and that the danger of interfering with the epiphyseal growth and the sensibility of the skin present real limitations to the method. By careful technic it is possible to avoid immediate skin irritation, but as yet he thinks we cannot always avoid late ulcerations, their onset being delayed occasionally for years. This method of therapy he believes to be of less value than the exposure to direct sunlight in high altitudes, but he considers its value lies in its more general applicability.

Schede,[6] working in Lange's clinic, also writes favorably of Roentgen ray therapy in bone and joint tuberculosis. He believes only small "doses" should be employed, since the tubercular tissue reacts much more than the skin or healthy tissue. Cases with sinuses have shown the best reaction, and he has noted no interference with epiphyseal growth. A healthy epiphysis should, however, always be protected. He believes that the method should be combined with general hygienic treatment and orthopedic methods. A damaged skin, cold abscesses, fungus growths threatening perforation, are contraindications to the use of the Roentgen rays.

Bardenheuer[7] reports 40 cases of peripheral tuberculosis treated by heliotherapy at a high altitude. Of these 40 he considered the severity of the disease to be slight in 10, moderate in 11, and great in 19. Of these 19 serious cases, 10 were over twenty years of age, and 13 had "a splendid result." Seven of them he considers completely cured. He believes there may be an exacerbation of the disease in cooler weather. Altitude seems to be of much importance because of the greater therapeutic value of the sun's rays.

Baetzner[8] writes enthusiastically of the trypsin treatment of surgical tuberculosis. After much trial he has adopted the preparation of Fairchild Brothers and Foster, "Injectio Trypsini," which he finds satisfactory as to sterility, and both active and stable. Using himself as a control, he has experienced no ill effects. When the trypsin has been injected into abscess cavities there has been a marked change in the contents of the sac, the pus becoming at first syrupy and brownish and then like meat juice. In a few cases alarming symptoms have appeared and suggested an acute inflammatory phlegmon with rigor and high temperature. These have disappeared in from 24-28 hours, the swelling going down in from four to six days. The reaction in the great majority of cases has been only a slight smarting pain at the moment of the stab and sometimes a slight rise of temperature. The synovial hygromata, for example, of the flexor and extensor sheaths of the hand with "snow ball crunching" have improved under the injections very rapidly and the function of the tendons has improved also. Bones extensively diseased in children have shown what he considers marked and surprising regenerative changes in the skiagraphs. In abscesses after puncture he injects 1-2 c.c. of the Fairchild preparation diluted with ten parts sterile physiological salt solution. He avoids reddened areas. Two or three injections frequently suffice. In sinuses he injects into the walls of the sinus and into the surrounding parenchyma. In the synovial hygromata he injects into the synovial sheath, starting with 2-10 to 5-10 c.c. and after 3-4 injections using larger doses. In joints he injects directly into the parenchyma 1-2 c.c. of trypsin without the dilution with salt solution, using an ordinary hypodermic syringe. The article is apparently somewhat enthusiastic, although the author seems quite convinced that in trypsin he has a valuable therapeutic agent in surgical tuberculosis.

Sattler[9] has used, not trypsin but concentrated carbolic acid as an injection in "many" cases of surgical tuberculosis. He believes that the cases treated with his carbolic injections improved much more rapidly than those treated by other methods. Multiple foci or cases associated with pulmonary tuberculosis do not show a satisfactory reaction. He injects directly into the lesion at the point of tenderness a few drops, up to 15 minims, of concentrated carbolic acid, and repeats this injection every 2-3 weeks, according to the reaction. Age is no contraindication, although children react more quickly. There is little pain, and healthy tissue does not seem to be damaged. (Just why does not appear.) He says that there are no general symptoms.

(Ed. Note.—We report these forms of treatment without personal knowledge of their efficiency or safety. We have had slight experience with the use of the "injectio trypsini" of Fairchild and Foster in an out-patient clinic in the treatment of persistent sinuses. This slight experience has been favorable and leads us to continue. There seems, moreover, to be a growing tendency among many clinicians to seek again for antiseptics in the treatment of infections, and these reports are the most suggestive which have come to our notice in this connection.)

Robert Jones's[10] conclusions are always of great value from the fullness of his experience

and the keenness of his observation. In a recent article dealing with tuberculous disease of the bones and joints, he mentions the diagnostic aids and the principles of treatment upon which he relies. As to diagnosis, assuming that the vague history and insidious onset are characteristic, the next factor upon which he depends is the temperature. A subnormal morning temperature of 97.5 F. or less, with an evening temperature of 99, he considers to be practically pathognomonic of tuberculosis. A higher temperature, of 100° or more, suggests either a septic infection pure and simple or complicated with a tuberculous lesion. If the evening temperature is not high enough to suggest a septic infection and the morning temperature is not subnormal, then the case is probably the result of trauma and represents simply a contusion of the joint. The principles of treatment upon which he relies are, first, complete physiological rest; second, good nourishing food, especial importance being attached to butter, "drippings," jam, and sugar, with an unlimited allowance of good milk; third, fresh air; fourth, sunshine. Mr. Jones thinks that experience does not indicate the truth of the theory that by a certain amount of use the patient may give himself immunizing doses of his own tuberculin. He does not consider that the use of tuberculin is usually necessary for recovery, at least in children, and if this treatment is undertaken he calls attention to the fact that it is more often bovine than human. In adolescents the systematic use of tuberculin ought to be of great advantage, but the problems of administration and the indications for its use are not simple.

Pirie,[11] writing on the reformation of bone after resection, discusses tuberculous osteomyelitis. He states that it is not common, occurring 50 times in 8800 x-ray cases. The diagnosis can, in his opinion, be almost certainly made from the x-ray alone. The skiagrams of his two cases would be considered by many to be suggestive of a chronic pyogenic osteomyelitis, one of three months' duration with a periostitis, and the other following a sprained ankle a year previously. He resected four to five inches of the shaft in each case, and no microscopical examination or inoculation tests are noted. The more recent case regenerated in five weeks, while the second case required two years to restore the bone shaft. He is apparently in accord with Macewen's views as to regeneration of bone, and advises the careful preservation of the periosteum as "a limiting membrane" in the formation of new bone of normal shape. If the laying down of a new bone of proper size is unduly slow, he advises a fracture of the slender shaft as a stimulus to new bone formation.

(Ed. Note.—We have seen proved tuberculous osteomyelitis of the shafts of the long bones very, very rarely. Of its existence there seems to be little doubt, but the question has been properly raised as to whether these cases do not more commonly represent a mixed infection of pyogenic organisms with tubercle bacilli, this mixed infection favoring the more diffuse nature of the lesions.)

Wheeler[12] also advises resection in tuberculous disease of the lower end of the femur between the lower epiphysis and the shaft. He saws across the bone two or three inches above the metaphyseal line, and twisting the lower piece of bone free, wrenches it from the epiphysis. The periosteum previously separated is sewn together. The x-rays show good regeneration.

Brandes[13] reports on the end results of radical operation for tuberculosis of the knee. His material is obtained from the cases operated upon by Helferich in the Surgical University Clinic in Kiel from 1899 to 1907. Twenty-six children were operated upon. In 19 a resection was done, in 4 an arthrectomy, in four an amputation. Three of the resections had later flexion contractures. Fourteen other cases of resection examined had firm osteal ankylosis in a useful position of extension and the patients are able to work and earn their living.

Osgood[14] has reported 28 cases of excision of the knee performed by various orthopedic surgeons at the Massachusetts General Hospital from 1907 to 1912. In 14 of the cases either no sutures, absorbable sutures, or wire sutures were used to maintain apposition of the bone ends. Of these there were 3 subsequent amputations, and in 12 union was delayed three months or more. In 14 either malleable iron bone plates or aluminum wire bone clamps devised by Goddu were used, and in these there was only one subsequent amputation in a very unfavorable case treated afterwards outside the hospital. Firm union occurred in two months or less in 10, and every case except the amputated one finally obtained firm union. The plates or clamps were subsequently removed because of irritation in four cases, without further trouble. The belief is expressed that some method of obtaining accurate and firm apposition of the bone ends immediately following the excision is most desirable, and that if this is accomplished postoperative pain is less, firm union more quickly takes place, and a useful limb is almost always obtained.

Cases of tuberculous rheumatism, so-called, continue to be reported by Poncet,[15] Popper,[16] and Griffith.[17] We could wish for more convincing proof of the tuberculous nature of these arthritides, but there seems to be no doubt as to the frequent association of what seems to be a toxic polyarthritis with lesions of the lungs, glands, and bone, known to be of a tuberculous nature. Moreover, in substantiation of the claim that these arthritides are caused by the toxines elaborated in the tuberculous lesion, is the fact that increase in the joint symptoms follows small injections of tuberculin. Poncet advises operative treatment in the cases of "inflammatory" tuberculosis in which ankylosis

has occurred, declaring that resection with early mobilization gives brilliant results.

(Ed. Note.—To a limited extent this advice of Poncet may be wise in lesions of the elbow and possibly of the shoulder and wrist, but the experience of most men who have devoted attention to arthroplastic operations emphasizes the peculiarly unfavorable nature of old tubercular joints for these mobilizing operations. An exacerbation of the disease frequently takes place and the results by and large have not thus far been satisfactory.)

POLIOMYELITIS, SPASTIC PARAPLEGIA, AND OBSTETRICAL PARALYSIS.

Poliomyelitis. Colliver,[18] after a study of 16 cases in the recent Los Angeles epidemic, calls attention to "a peculiar twitching, tremulous, or convulsive movement" of certain groups of muscles, lasting from a few seconds to nearly a minute. It is greater than a tremor, and not so long as a convulsion. It occurs in the preparalytic stage. The face, the limbs, or the whole body may be affected. It occurs at intervals of about an hour, and being of very short duration is easily overlooked. There may be also a peculiar "hydrocephalic" cry.

(Ed. Note.—This early prodromal sign has frequently been observed in monkeys and has been one of the methods by which the onset of a paralysis could be predicted. It frequently is of longer duration and of more frequent occurrence in monkeys than Colliver has noticed in human beings.)

Müller[19] agrees with the findings of Lucas that in the early stages of an infection with the virus of poliomyelitis there is an increase in the quantity of spinal fluid, with moderate lymphocytosis and increase in the albumen. The fluid is, however, sterile to ordinary culture materials. Unless there is a mixed infection he has found in the blood a leucopenia with a relative increase in the lymphocytes and the eosinophiles.

McIntosh and Turnbull[20] have reported four attempts to transmit the virus of poliomyelitis from human beings to monkeys by intradural and intraperitoneal injections. The first two cases were unsuccessful, but in the third and fourth they obtained a typical picture. Historically, their report is of interest in that they state that this is the first work of the kind done in England.

Neustadter,[21] citing the report of Romer of a form of flaccid paralysis occurring in guinea-pigs, reports that two guinea-pigs living in a cage beneath a monkey which was suffering from poliomyelitis and had a nasal discharge, showed typical paralysis. He was able to transmit the disease through the nasal membrane in at least one case, which showed characteristic lesions of the cord and brain.

(Ed. Note.—As far as we are aware, this is the first time in which experimentors have observed a transmission of the experimentally produced disease without definite inoculation. Attempts have repeatedly been made to transmit the disease by contact, by means of mixing the nasal secretion of acutely sick cases with the food of healthy susceptible monkeys, and in various other ways. These attempts have been failures. It is a significant fact also that experimentors have not contracted the disease.)

Brown,[22] in reporting the Los Angeles epidemic, calls attention to the importance of quarantine and isolation hospitals, oiling of the streets, and general municipal attention at the first sign of an epidemic, but the facts only show coincident cases in families and localities. He believes that urotropin is harmless, but of little efficacy.

By far the most important contribution to our knowledge of the virus of poliomyelitis has been the successful cultivation of the organism by Flexner and Noguchi.[23] The culture material is sterile rabbit kidney in a human ascitic fluid covered with a layer of paraffin oil in order to furnish anaerobic conditions of growth. The usual sized portion of sterile rabbit kidney is first placed in the test tube and a fragment of corresponding size containing the virus removed from the cerebrum or other part of the brain or spinal cord is added. Upon these about 15 c.c. of sterile human ascitic fluid is poured, and finally about 4 c.c. of paraffin oil. The ascitic fluid must be originally sterile. Fractional heating or sterilization renders it unsuitable. The tubes are placed in the thermostat. If gross contaminations have been excluded the tubes show a faint opalescence appearing in about five days around the fragments at the bottom of the tube. The opalescence spreads to other portions of the tube in three to five days more. When the growth is well established in this fluid media it may be transplanted onto media made solid by the addition of a 2% nutrient agar, and on this small colonies become evident to the naked eye. Uncontaminated cultures may be stained best by the Giemsa or Gram method. The microorganism consists of globoid bodies measuring from 0.15 to 0.03 of a micron in diameter arranged in pairs, chains, and masses, according to conditions of growth and multiplication. Typical experimental poliomyelitis has been produced in monkeys by the injection of this artificially grown virus.

Spitzy[24] has abandoned the plastic transplantation of the trapezius in paralysis of the deltoid. He considers the operation both difficult and dangerous, and in one of his cases the flat transplanted trapezius became later rounded and slipped forward or backward in every abduction of the shoulder. He has more lately employed the following operation and reports its success in two cases. A transverse osteotomy of the humerus above the insertion of the pectoralis major allows the outward rotation or the lower fragment. The bone is allowed to heal with the arm in the elevated position in a

moulded (plaster of Paris) splint made before the operation. By this manoeuvre the pectoralis is brought under greater tension, which is diminished by elevation. The clavicular portion of the pectoralis takes the place of the deltoid, and although the child cannot lift heavy weights it can elevate the arm in a vertical direction.

Lange and Vulpius have both performed osteotomy of the humerus and outwardly rotated the lower fragment in cases of obstetrical paralysis.

Gallie[25] reports successful results, which he considers permanent, from the operation which he independently devised of retaining paralyzed feet in good weight-bearing position by fastening the paralyzed tendons as stays to the tibia or fibula. After the periosteum is divided by a linear cut a groove is made in the bone, the tendon drawn up to the proper tension and the periosteum sewn over it. A similar method was reported favorably by Codiville in 1900.

Spastic Paralysis. Werndorff,[26] in considering the indications for section of the posterior nerve roots in spastic paralysis believes that the elimination of the contractures represents the first and chief problem in treatment. This he is sure should always be done before Foerster's operation is considered, and he thinks that in most cases this will be sufficient. His conclusions are in agreement with those of Harris,[27] who has made a study of the end results of cases operated upon at the Children's Hospital in Boston. These were the results of tenotomies and myotomies and have been in the main most satisfactory. Foerster[28] himself now pleads for a very careful consideration of the indications before his operation is attempted. First, the pathological condition should be stationary or nearly so; second, sometimes it is a questionable method of interference after the condition has remained stationary for a long period (how long?); third, one must be very sure that the spasticity is not due to tumors, syphilis, or Pott's disease; fourth, the operation is of little value unless there is excellent mentality, since prolonged after-treatment and muscle training is absolutely essential. Foerster believes the operation less applicable to the arms than to the legs.

Obstetrical Paralysis. Lange[29] reports 17 cases of distortion of the shoulder joint and obstetrical palsy. Five of these he considers as real paralysis, twelve of distortion. The clinical pictures are similar. The x-ray showed in no case a dislocation. The main diagnostic sign is the pathognomonic position of the arm and limited function. He believes that the treatment should be carried out under these headings: 1. prophylaxis against contractures. In adults exercises; in children plaster of Paris bed with the arm outwardly rotated, and passive motions instituted. 2. In inveterate cases redressment under an anaesthetic (this up to one year). 3. In old cases (over one year) osteotomy of the humerus at the mid point and outward rotation of the arm.

(To be continued.)

Reports of Societies.

WORCESTER DISTRICT MEDICAL SOCIETY.

MEETING OF DECEMBER 10, 1913.

President, HOMER GAGE, M.D.; Secretary, ERNEST L. HUNT, M.D.

The secretary's report approved without reading. A communication from the Committee on State and National Legislation of the general society was read, and a local committee, consisting of Drs. Emerson, Duggan, Reed and Bragg, was nominated.

DR. WALTER E. BOWERS, in behalf of a committee of which Drs. Knight and Harrower were the other members, presented a memorial to Dr. Edwin Bayard Harvey. *Voted:* To file the memorial in the Year Book, and cause a copy to be sent to Mrs. Harvey.

DR. W. IRVING CLARK presented the report of the Committee on Public Lectures, outlining their plan for a series of lectures to be given on health subjects under the auspices of the society. He requested the advice of the society as to the program, place of meeting, and especially on the advisability of dealing with the sex question.

DR. HOMER GAGE: This matter is one of great personal interest to me. In the past the society as a body has not done as much work for the community as it might have. The questions presented by the committee are important, and I hope they may be decided rightly, and the committee empowered to carry out the plan. The location of the hall is important, and publicity is necessary in order to secure the first audience. I hope the members will express their opinions freely.

DR. T. E. MCEVOY: I doubt the advisability of presenting the last subject mentioned (Community Responsibility for the Prevalence of Venereal Disease). This is a difficult subject upon which to instruct the public, and would better be done in another way.

DR. A. C. GETCHELL: I move that we accept the report of the committee, with the understanding that the society is in favor of the scheme, and that it be referred back to the committee with power to act. Voted.

The president again called for an expression of opinion in regard to the presentation of the sex subjects. No one responding, the president said he thought that silence on the part of the members should be interpreted by the committee as implying doubt.

The president then introduced the speaker of the afternoon, DR. HOWARD LILIENTHAL, of New York City, author of a work on Imperative Surgery, surgeon to Mt. Sinai Hospital, frequent contributor to current medical literature, and announced his subject as

THE SUSPICION OF MALIGNANCY.

The speaker prefaced his paper* by saying that his treatment of the subject would perhaps be in

* See page 120 for paper in full.

more popular vein than strictly scientific, and expressed his hope for a free discussion of his paper. He also mentioned that a society had been recently organized calling itself The American Society for the Control of Cancer, with the object of educating the public on this subject.

DISCUSSION.

DR. HOMER GAGE: We have listened to an extremely interesting and timely paper, coming at a moment when a more determined and organized effort to instruct the public and the profession as to the need of early diagnosis and excision of cancer is under way. At present, all recognize that there is no cure except the knife. While promising work in various other directions is being done, it is yet too early to use any of them as a basis for general treatment. The new statistics of Dr. Lilienthal as to the frequency of cancer are most interesting to my mind, especially the uniformity shown in the figures obtained from different sources. No matter how the groups are subdivided, the general fact remains the same, which is proof to my mind that his figures do not lie. There is another important thing that I would like to add to what Dr. Lilienthal has said. There is a class of cases in which conditions exist which have been called by Bloodgood pre-cancerous. Such are the small ulcers appearing on the lips of elderly people, or small tumors of the breasts as certain cysts, which are prone to become cancer. Often we find in seemingly simple cysts little papillary projections, doubtless early manifestations of malignancy. This subject is urged upon the attention of all by the new association. I know that Dr. Lilienthal likes argument and hopes for a free discussion of his paper, which I am sure he will enjoy as we will profit by it.

DR. RAY GREENE: I recall how Dr. Lilienthal in undergraduate days disagreed with Dr. Fitz over a piece of liver. I have recently had several cases of sarcoma, which I treated with Coley's fluid, and had some correspondence with Dr. Lilienthal regarding that treatment. I would like to know his present opinion of that treatment.

DR. W. E. BOWERS: There always comes up in the mind of the surgeon the question of the necessity of a mutilating operation in early cases. Do not the fascia planes act as a dam to the progress of malignancy? Is there not a chance to do less severe operations if the cases are seen early? Many of us have seen these early cancers, in which the diagnosis has been proven by microscopic examination, removed by less extensive operation, fail of recurrence. This may be playing with fire. Will Dr. Lilienthal speak about that? We want him to feel that we are alive to this opportunity to learn of so high an authority.

DR. A. C. GETCHELL: The question of the frequency of malignant growths in adult women of apparently good health interests me. My opinion was recently asked by the librarian of our public library on a book by Brooks Adams called The Health Master. In the chapter on cancer the health master talks to a woman's club of sixty from the ages of thirty to sixty-five, telling them that eight of the number had cancer. The book states that some of the number looked queer, and in a few months eight had been operated on for cancer. While the author in his book has presented some true conditions, there are others which I know are not true. Is the proportion which he states correct?

DR. L. C. MILLER: What are we going to do with the patients whom we suspect to have cancer, and cannot prove it by ordinary examination? Special diagnostic procedures take time and tend to fasten the patient's attention upon the disease. What shall be our conversation to the patient? Are we to tell them our suspicions? Is it not better to leave them in the dark until we can confirm our diagnosis absolutely?

DR. M. F. FALLON: When I visited Mount Sinai Hospital Dr. Lilienthal was treating cancer cases by means of the x-ray and serums, and I would like his opinion on the value of that kind of treatment. Surgeons deserve great credit in trying to do away with operations. Perhaps one of the most prominent workers in this field is Fischera of Italy. He uses extracts of the human embryo in the treatment of inoperable cancer. No less an authority than Dr. William Mayo gives credence to the results which he has obtained, having been successful in a few cases. The rationale of this treatment is based on Cohnheim's theory of the origin of cancer,—that is, that it is caused by an irritant or injury. If this is true, embryonic cells are stimulated to invade the near-by tissues and run lawlessly. This constitutes cancer. Experiments show that at times extracts of healthy organs injected into healthy animals of the same species will destroy the same organ in that animal. Dr. Mallory has shown that an extract prepared from the scrapings of the stomach of a rabbit injected into another rabbit produces ulcer of the stomach, also solutions of the bile salts destroy the liver in the injected animal. Certain tumors in rats have been made to disappear by the injection of extracts from rat embryos. Fischera bases his work upon such facts as these. If it is true that the growth is due to lawless embryonic cells, then the injection of an extract of an embryo may cause the cessation of the development of the cancer. It is at least interesting to look into the investigations of such men.

DR. LILIENTHAL: I am glad that Dr. Gage spoke strongly of excision, and moderately in reference to other treatments. We have been deluged with such treatments as mesothorium and various serums with no success in the hands of many good men. It is probable that the x-ray, radium and mesothorium will cure superficial cancer by a destructive influence as efficacious as the knife. If I had an epithelium in the corner of my eyelid, I would go for x-ray treatment. But if I had a removable cancer inside of me, I would risk nothing but an operation. As for a precancerous stage, everyone who is ever going to have cancer is in a pre-cancerous stage. I should rather use the term a suspicious condition where one has a tumor that might develop into cancer. Do not temporize with chronic mastitis. I advise the removal of the entire mammary gland, without the muscles or lymphatics. Tell the patient she will lose the nipple. She will be satisfied when told that it is not cancer and never will be.

In reply to Dr. Bowers' question, when there is real cancer in the substance of the breast or connected with it, the best results are obtained with the more formidable operation; remove everything. This has been my uniform practice, and I have never regretted it. Some surgeons are satisfied to remove the fascia over the pectoralis major, but cancer is more apt to stand under the pectoralis minor. It is probably true that too much skin has

been sacrificed, a deep cancer being less apt to recur in the skin than anywhere else. Save enough to close the wound easily. This does not apply to large ulcerating growths.

To Dr. Greene's question in regard to Coley's fluid, I have some delicacy in mentioning it before the New York Society, and can never arouse a discussion. When I present patients who appear to have been cured, nobody says a word. When I ask why, they respond that a committee has investigated and decided that as many sarcomata get well without Coley's fluid as after its use. I was responsible for the postoperative use of Coley's fluid. I have a case operated on twelve years ago supposed to be a cyst of the chest wall involving the ribs, probably tubercular. At operation found it to be apparently sarcoma, and had a large piece out of the pleura before I knew it. The cut-end of the ribs had some of the growth in them. It is impossible to remove it completely. I gave an extremely guarded prognosis. Pathologist reported pigmented cell sarcoma. I gave Coley's fluid, and the tumor of the cicatrix disappeared. One year after an enlargement appeared. Again gave Coley's with again complete disappearance. I have presented this man three times before the New York Medical Society. In another case I removed part of the superior maxilla. Could not remove it all as the disease was so extensive. Closed it up, yet there was a hump on the left side of the nose remaining. In answer to the patient's inquiry, I said, "Oh, it is nothing. I will later clear it off." Gave Coley's fluid, and in a few weeks the tumor disappeared. Face assumed a natural appearance. This was a year ago. A week ago still appeared well. Pathologist's original report was malignant osteosarcoma. Now, he says, there were giant cells in it, and another pathologist also found them. Most giant celled sarcoma of the epulis type are nonmalignant. Such experience, however, makes me want to use Coley's fluid after every case. If I am doing wrong, my intentions are good.

Dr. Getchell's inquiry,—As to the frequency of cancer in ordinary adult women, I do not understand such a statement as he quoted from the Health Master. It seems as if they must have been cases of carcinophobia. Many people have moles, etc., which it is well enough to remove by operation. I do not believe any such number had cancer.

Dr. Miller,—As to what to tell the patient. I believe a patient suspected of cancer should have the benefit of every kind of examination. If the stomach, tell her that ulcer is very common, and that you want to find out if she has one. Tell another member of the family your real suspicion. One ought not to quiet the patient's mind until his own mind is quieted.

To Dr. Fallon,—I have tried the method of injecting patients with emulsions from the whole cancer, in the hope that it would act as a vaccine. I have had but eight cases. One had a recurrence. The others are not heard from. There is no doubt in my mind that some cases of cancer are cured without cutting. Whether it is a germ disease or not, it is certainly a disease of chemistry. The new born and embryos do not have sarcoma, though they may have other tumors. As the investigators do not know what part of the embryo prevents it, it was therefore rational to use the whole embryo. The thymus has been suggested as the preventive force, because it atrophies in later life. Rhodenberg has had cures with the thymus, both in extract and in feeding the whole gland.

A professional friend of mine brought his mother to me for cancer of the breast. I did a complete operation. Two years after it recurred, forming a tumor of the chest mall, a hard, red, elevated nodule about the size of a filbert. The patient had said nothing about it. Under local anesthesia I removed all I could, and found it bound down to underlying bone. A microscopic examination showed that this was a carcinoma of the same type as the parent tumor. The son then took the case into his own hands. Dr. Rhodenberg furnished the thymus extract. The wound healed, and the patient is well now, but other cases have not recovered. Dr. Carrel agrees that it is a good and tenable theory. The blood of the infant may have some substance that rejuvenates and prevents the cancer getting hold.

FRANKLIN COUNTY DISTRICT MEDICAL SOCIETY.

The bi-monthly meeting of the society was held in Greenfield, January 13th. A letter was read with reference to a bill now before the legislature regarding the revelation of professional secrets in court on the part of physicians and nurses. The suggestion offered was that the words "not be urged" should be changed to "not be compelled." Dr. G. P. Twitchell of Greenfield read a paper on the Treatment of Gastric Ulcer. The paper was discussed by Drs. H. G. Stetson and Charles F. Canedy of Greenfield and by Dr. Philbrick of Northfield. Dr. Paul W. Goldsbury of Warwick read a paper on Observations on the Sense of Smell, and gave a demonstration.

Book Reviews.

The Treatment of Rheumatic Infections. Press of Parke, Davis and Company.

This monograph is a statement of the case for phylacogen treatment of the so-called rheumatic arthritides.

Forty-Fourth Annual Report of the State Board of Health of Massachusetts. Boston: Wright and Potter Printing Company. 1913.

This volume records the official activities of the Massachusetts Board of Health for the fiscal year ended Nov. 30, 1912. The general report particularly discusses progress made in antityphoid inoculation, in the knowledge and control of poliomyelitis, and ophthalmia neonatorum, and the maintenance of isolation hospitals by cities or towns. Among the recommendations for the new year may be mentioned the need of a central authority to supervise tuberculosis in Massachusetts. The remainder of the volume consists of supplementary special reports on water supply, sewerage, food and drug inspection, cold storage, slaughtering, dairies, plumbing and other works in hygiene, with papers by members of the board, and tabulated statistics.

THE BOSTON
Medical and Surgical Journal

THURSDAY, JANUARY 22, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

THE MASSACHUSETTS BOARD OF HEALTH.

THE inaugural message of Governor Walsh devotes some attention to public health. That part of his message is as follows:—

"There is no more important function in the government than to care for and protect the public health. In the earlier development of the country this truth was not so well recognized; but Massachusetts is entitled to the credit of having led the way among the Commonwealths in the establishment of a State board to safeguard the health of its people. Public health questions in this State were first considered by a commission appointed in 1849, and in 1869 the State Board of Health was created. Down through the intervening years the board has not only led the way in the study of health problems, but has secured the enactment of a body of health laws which have been the model for legislative action in other States.

"Changes in conditions and the great increase in the volume of work of the board would now seem to demand such a reorganization of this department as would place it among the paid boards, with an executive officer armed with authority and charged with the responsibility of supervising the administration of the health laws of the State. With this in view, I recommend the establishment of a salaried Board of Health, with a health commissioner appointed by the board and subject to the approval of the governor. Provision should be made for sufficient salary for the health commissioner to insure the services of a man of training and capacity to fill this important position, probably the most important in the public service of the Commonwealth. The salaries of the members of the board, whose duties would be largely advisory, need be little more than nominal, because the experience of the past demonstrates that men of commanding ability in the study of health problems will give of their time and service to the State."

The praise of Governor Walsh for the Massachusetts Board of Health is richly deserved. The bulletins of this board have been accepted as models not only for other States, but for the United States Public Health Service. Some of the many achievements of the State Board of Health have been the production and the free distribution of diphtheria antitoxin and smallpox vaccine at a time when such a step was regarded as socialistic. Practitioners in the State have never failed to secure a sufficiency of diphtheria antitoxin in an epidemic. The advertisements of anti-diphtheritic sera do not allure the physicians of Massachusetts, because reliable antitoxin is prepared and furnished by the State Board of Health. Recently the Board of Health has prepared and distributed free typhoid vaccine for immunization against typhoid fever, and in its campaign against infantile blindness it has furnished silver nitrate to all practitioners. Among the many investigations of the State Board of Health, there come to mind the classical studies on the filtration of water supplies and the more recent studies which led to the discovery of the insect that may play a part in the transmission of poliomyelitis. These are but a few of the accomplishments of a board that Governor Walsh so justly praises.

The Governor believes, and others share his belief, that the prodigious advances in the nature, causes, prevention and control of disease necessitate a new machinery for the State Board of Health. In his recommendations he has suggested a reorganization somewhat similar to that undertaken in New York, and gives a bare outline in his message. He believes in a single highly-paid commissioner of health, with an advisory board, whose members are to be paid a nominal salary. At present the entire authority is vested in a board the members of which are unpaid. The executive officer is the secretary of the board and derives his authority from the board. All matters of importance are decided by the board, of which the active executive officer is not a member. In his subordinate capacity the secretary may act only as the delegate of the board; he cannot speak with the authority of the official state health department. At times it has happened that difficult problems

have had to await the meeting and action of the board before authoritative action could be taken.

We believe that there is much to be said in favor of the recommendation of Governor Walsh. The details of the suggested reorganization need careful consideration and will be discussed in these columns in the near future. We believe that everything concerning the State Board of Health, its policies, its organization, its personnel, is of vital importance to the medical profession of the State. Before any change from the present machinery of the health force of the State, which has served so long and so creditably, is put into effect, all phases of health administration must be carefully surveyed.

The State Board of Health depends for its usefulness upon the support and coöperation of the rank and file of the medical profession throughout the State. It must in the future, as it has in the past, assume a wise leadership over the physician in matters of public health.

The medical profession, which is the actual exponent of all health activities, should manifest no slight interest in any suggested reorganization of our State Board of Health. It is the privilege and duty of the physicians of Massachusetts to make themselves heard in this important matter.

MEDICAL LEGISLATION. THE PRACTICE OF MEDICINE AND DENTISTRY.

THE State of Massachusetts, whose position on most public questions has always been an advanced one, has been singularly behind some of her sister states in her attitude toward legislation for the regulation of the practice of medicine and dentistry. It is one of the few states at the present time that will license a dentist or a physician who possesses no evidence of having graduated from an institution chartered to grant a diploma for efficiency in either of these two professions. She is one of the small number of states that permits its governor to appoint the boards of registration for the qualification of candidates who must pass the state board examinations before they may practice, thus making these boards under the influence of politics to just the extent that the incumbent of the governor's office is subservient to political influences.

The opposition to legislation looking to the betterment of the practice in dentistry and medicine and the safeguarding of the health interests of the public has come not only from those whose personal and pecuniary interests have been involved, but to a certain extent from those obsessed by the idea that legislation restricting the practice of these professions to those coming up to the prescribed standards of ethical and educational qualifications would be an infringement upon the rights of personal liberty. The bulk of the opposition is, of course, from those who could not meet increased educational requirements and are possessed of no ethical standards.

It is very desirable that this state should emancipate itself from a position so highly unsuited to its record in other matters. State pride ought to operate to accomplish this, even if there were no better reasons. In the issue of the JOURNAL for Jan. 1 (Vol. clxx, p. 24) we commented at length editorially on pending medical legislation relative to the practice of dentistry in Massachusetts. The bill proposed for enactment this year by the Massachusetts Civic League relative to the practice of dentistry is one, which, if passed, will go a long way toward putting the state in a position in accord with her importance as a progressive leader in legislation for the welfare of her citizens. Its passage, practically as it stands, should be favored by every one having at heart the betterment of conditions surrounding the practice of dentistry. The physicians and dentists of all sections of the state should take the trouble to enlighten their senators and representatives with respect to the importance of the enactment of right legislation in this respect, and there would then be no difficulty in getting a proper statute upon the books. This bill does not go as far as it should, in our opinion, in correcting the danger of political domination of appointment to the Board of Registration. It would be better that the governor should be provided with a list of available competent men, selected by the state dental societies, and that from this list he should make the prescribed appointments and fill any vacancies. This is the way the matter is managed in a good many states.

The second section of the bill deals with the matter of what shall constitute an acceptable dental school so far as time spent in study is concerned, and also with rules governing the licensing of graduates of dental schools by the registration board and the procedure to be fol-

lowed when a dentist desires to change his residence and practice to another state.

The third section deals with the penalties attached to practicing without proper licensure or under false colors. It also deals with the question of dental assistants. Last year an effort was made to secure such legislation as was necessary to establish this order of dental assistants. It was defeated by the attitude of the state board toward the measure, as well as by the opposition of those who thought their interests were being jeopardized, or who imagined they saw in the bill a portal of entry for those who, without any adequate training in dentistry, would attach themselves to "dental parlors," and do a poor grade of work. This year's bill has been improved in this respect by abundant safeguarding of those features that doubts were expressed about in last year's Dental Nurse Bills, so that there would now seem to be no excuse for not enacting this very beneficial piece of legislation. In a bill that promises to furnish a better dental law than we at present have, it is extremely desirable that there should be no provision which cannot be enthusiastically supported by a united dental profession. It should not carry any provisions the import of which is not clear, in the hope that it may go through as a rider.

Such attempts would jeopardize the passage of the bill, the main provisions of which outweigh in importance the possible good resulting from the passage of the rider. In the proposed bill the clause referring to the dental assistant is a very important clause, though not given much prominence in the text of the bill. Dental prophylaxis cannot be carried out unless some provision is made whereby both in private practice and in public clinics the necessary attention can be furnished. The modern expansion of the technic of dental and oral surgery takes all the time and skill of the dentist, and some help must be given him to enable him to meet the demands of the prophylactic side of his work, which must otherwise be neglected, to the detriment of the public. It is more feasible to have the grade of skill required for this department of dental work provided by the dental assistant, who should be licensed and, before being licensed, sufficiently trained so that she (or he) may use such instruments and perform such technic in the mouth as is necessary to accomplish the purposes for which they are licensed. Exactly what the dental assistant may be permitted to do should be even more specifically outlined than it is in the present bill, and any evasion of the provision which makes it imperative that their work should be done under the supervision of a registered dentist should be punishable by an immediate revocation of the license. The penalty for improperly engaging in dental practice by such a nurse or assistant would then be at the door of those entrusted with the proper enforcement of the laws governing the practice of the dental profession.

Dental charlatans with a dental degree, obtained without proper qualification, should not be tolerated. No one else would make any improper use of such assistants, and without improper registration of dentists there would be no danger of the establishment of so-called "dental parlors," where work detrimental to the public and the dental profession might be carried on. Therefore provision should be made that these assistants before being registered should prove by practical tests their mastery of the necessary technic. Through her activities dental prophylaxis may not only actually be carried out by those who will come often enough to their dentist to have their teeth properly cleaned, but an educational campaign on the home care of the teeth might be launched.

Section four deals with the revocation of licenses and the redress that may be had by one who considers himself aggrieved in this respect.

Section five imposes fine or imprisonment or both as the penalty for practising without license or employing an unlicensed dentist (not a dental nurse) as an assistant.

A great deal has been said of late apropos of the importance of a clean mouth. The relation of work of this sort to the health of the community, and particularly in regard to the health of school children is receiving much emphasis. There is, however, a tendency to go to extremes in this matter. Too much should not be claimed. The mouth is simply one of the portals of entry for infections detrimental to the human economy. Infections are only one of the sources of human illness. The support which a reasonable presentation of these claims might attract to this bill should not be sacrificed by the exploitation of unsubstantiated theories on the part of those whose horizon is limited by the walls of the bucal cavity. The possibilities of harboring infections and contagious diseases, the causation of many constitutional infections, such as arthritis, nephritis, Riggs' disease, etc., though not

playing a common rôle in the first two instances at least do, without doubt, cause in some cases a disastrous train of sequelae. Of equal importance with the occasional occurrence of the above-mentioned systemic disturbances traceable to the mouth and teeth are the many indefinite and intangible consequences of dental caries whose effects are manifested in digestive disturbances, poor nutrition, and lack of assimilation of food because of faulty mastication. In these ways the maximum of efficiency of individuals may be kept below par to such an extent that they cannot play their full part in the world's work. It would seem that a measure looking to the raising of the standards of efficiency of her citizens should make a strong appeal to the legislators of the state.

It is to be hoped that this year's general court will carefully consider these features of the Dental Bill when it comes before them, and give Massachusetts an act regulating the practice of this profession of which she need not be ashamed.

THE HELPFUL UNFIT

ONE of the newest and most propitious experiments for the solution of the problem of industrial waste, is the chance afforded feeble or partly disabled or convalescent people in hospitals and asylum workshops to support themselves by doing useful work. Both in this country and abroad there have been successful attempts to find work for people unable, under the present system of production, to gain all they need for a livelihood. The prospect is promising that knowledge will be gained which will mean changes in charity methods sufficient to encourage self-reliance and efficiency in many disheartened workers.

Thus far such experiments have proved the decided money value of such work, done despite obstacles. Supplies worth many thousand were produced the summer past by patients on the hospital farm at the State colony at Gardner, Mass. A pottery established within two years in connection with a hospital on the Pacific Coast has enabled tuberculous girls to pay their expenses under sanatorium treatment and to learn a self-supporting trade. The men admitted to the Otisville Sanatorium of the New York City Health Department are required to do such work in and about the institution as they are fitted and able to do and as is salutary for them; and they are much better off thus occupied. Five patients in an Eastern hospital last year made and sold $6,000 worth of pottery. At the Bedford Sanatorium for consumptives of the Montefiore Home in New York, vegetable gardening is done by the patients, sufficient at least for the needs of that institution. Feeble-minded patients under Dr. Fernald and Dr. Tuttle at the schools and hospitals at Waverley, Mass., under Dr. Laehr at the Hans Schoenow Hospital in Berlin, Germany, and in other places where craft work has been instituted, have made an excellent showing.

In this connection should also be mentioned the work done by Dr. Herbert J. Hall of Marblehead, Mass., in the treatment of patients through systematized work. The accomplishments of this institution in connection with various forms of handicraft are very definite and indicative of the possibilities of such systematized activities wherever the handicapped may congregate.

Such workers are not expected to be trained in this way for success in the more skilled trades; but certainly they can be taught the more simple arts of hand-weaving, metal-working, pottery-making, and cement working. Men and women thrown out of employment in a particular trade because of some special unfitness are by no means of no service at all. The unfeeling should have no right to speak of them as human derelicts, "fit only for the scrap heap." The problem, states the *New York Evening Post*, is to find and organize the sick and discarded workers, teach them work that they can do, and so by grading work to their ability, restore to them their self-respect and their sense of having a recognized place in society. Those who have been studying the experiments under way are predicting a system of labor supplementary to the present system of regular industries which involves so much waste. The burden of supporting the sick and idle will become too heavy, they assert; and then will be devised some general social policy of training the imperfectly fitted people, now often allowed to throw away their lives in sadness and neglect, to use what productive power they have for themselves and the community in which they live.

It should finally be remembered that the work of the physically and even mentally handicapped may often through previous training be of a far finer quality than that of the average so-called well person and that this is an asset to which the state and the community should give due regard.

MEDICAL NOTES.

SMALLPOX ON THE "OHIO."—Report from Washington, D.C., states that there occurred on Jan. 8 the fourth death from smallpox in the epidemic of that disease aboard the battleship *Ohio*.

THE "NEWARK" AS A QUARANTINE VESSEL.—It is announced that the United States second class cruiser *Newark*, now stationed at Guantanamo, Cuba, is to be transferred from the Navy to the Public Health Service, and will be placed at Providence, R. I., to serve as a quarantine vessel.

AN IMPORTANT MEDICAL AFFILIATION.—It is announced in *Science* that the Cleveland (Ohio) City Hospital is to become affiliated with the medical school of Western Reserve University. The sum of $1,000,000 has recently been raised for the further endowment of the school.

"The agreement which will be entered into by the city and the university will provide that all members of the visiting staff of the City Hospital shall be nominated by the trustees of Western Reserve University upon recommendation by the faculty of the school of medicine. The visiting staff will have absolute authority over the professional treatment of all patients of the hospital. The director of public welfare will be the administrative head of the hospital. The university will have all teaching and research privileges."

BRITISH MEDICAL NEW YEAR HONORS.—Relatively few medical names appear this year on the list of New Year honors in England. Sir Christopher Nixon, M.D., a former president of the Royal College of Physicians of Ireland, is made a member of the Irish Privy Council. The only new medical baronetcy is conferred on Dr. Sir Thomas Joseph Stafford, medical commissioner of the local government board in Ireland. Knighthood is conferred on Surgeon-General A. T. Sloggett, R.A.M.C., director of the British Army Medical Service; on Dr. T. B. Nariman, of Bombay, physician to the Parsi Lying-in Hospital in that city; and on Dr. Harry Brookes Allen, professor of pathology and dean of the medical faculty in the University of Melbourne. Sir Rickman Godlee, president of the Royal College of Surgeons of England, is promoted Knight Commander of the Royal Victorian Order.

FRENCH AND SWISS MORTALITY STATISTICS.—The mortality statistics of France for 1911, published this month in Paris, show a total of 775,088 deaths, as against 704,770 in 1910. Of these, 86,113 were caused by tuberculosis, 31,768 by cancer (as against 27,306 from the same cause in 1906), and 29,470 by the epidemic infections. In Paris in 1911 the tuberculosis death-rate was 380 per 100,000, that of Boston in 1910 being 175. It is noted that in 1861 there were but 50 lepers in Paris. There are now about 300 in that city, and 300 more in the rest of France. A commission has been recently appointed by the ministry of the interior to investigate this alarming increase.

In Switzerland the total death-rate has varied little in the past fifteen years. In 1899 it was 25.9 per 1000 in Berne, 21.9 in Basle, and 20.9 in Zurich. In 1907 the rates were 27.7 in Berne, 21.2 in Basle, and 16.8 in Zurich.

BOSTON AND NEW ENGLAND.

BOSTON DISTRICT HOMEOPATHIC MEDICAL SOCIETY.—At the annual meeting of the Boston District Homeopathic Medical Society, held in this city recently, the principal address was by Dr. Stephen H. Blodgett, the retiring president, on "The Press, the Public and the Medical Profession." The officers elected for the coming year are Dr. Orville R. Chadwell, president; Dr. Conrad Wesselhoeft, secretary; and Dr. Edwin W. Smith, treasurer.

COMPARATIVE NEW ENGLAND DEATH-RATES.—The comparative death-rates of five of the New England states in 1913 were as follows: Rhode Island, 15.4 per 1000; Massachusetts, 14.7; New Hampshire, 13.6; Maine, 12.6; and Vermont, 12.2. It will be observed that these rates are approximately proportional to the density of population in the respective states.

BOSTON MILK AND BABY HYGIENE ASSOCIATION.—At the regular January monthly meeting of the Boston Milk and Baby Hygiene Association, statistics were presented showing that during the year 1913 the Association cared for 3421 babies, as against 3021 in 1912, an increase of 13%.

HOSPITAL BEQUESTS.—The will of the late Alfred Jones, who died at Boston on Jan. 8, was

filed on Jan. 13 in the Suffolk probate court. It contains bequests of $1000 each to the New England Hospital for Women and Children, Boston; the Corning (N. Y.) Hospital; and the Women's Medical College, Philadelphia.

NEW YORK.

AMERICAN COLLEGE OF SURGEONS.—The board of regents of the American College of Surgeons held a meeting on Jan. 9 at the Waldorf-Astoria, the purpose of which, in addition to the transaction of routine business, was, as stated by Dr. John B. Murphy of Chicago, to discuss ways and means of advancing interest and opportunity in higher education in surgery, and to take steps for the provision of a home for the college, so that the stimulation of this uplift plan may be more effective over the entire country. At the meeting the names were ratified of 1,000 surgeons who were proposed as fellows of the college at its first meeting at Chicago in November last.

MONEY FOR ORTHOPEDIC DISPENSARY.—At a concert given at the Waldorf-Astoria on Jan. 9 the sum of $5,000 was raised for the New York Orthopedic Dispensary and Hospital.

MORTALITY STATISTICS.—The weekly reports of the Health Department show that the mortality in the city during the month of December represented an annual death-rate of 13.33, as against 12.64 in November and 14.21 in December, 1912. Among the diseases in which there was an augmented fatality were the following: The weekly average of deaths from measles increased from 6.25 in November to 9 in December; the weekly average from scarlet fever, from 4 to 5.25; from diphtheria and croup, from 19.75 to 22.75; from influenza, from 4.25 to 7.25; from acute bronchitis, from 13.75 to 15.25; from pneumonia, from 81.75 to 107; from bronchopneumonia, from 82.25 to 85; from cancer, from 81.25 to 83; from apoplexy and softening of the brain, from 19.75 to 23.25; from organic heart diseases, from 192.5 to 208; from hernia and intestinal obstruction, from 10.25 to 15.25; and from Bright's disease and acute nephritis, from 107.5 to 113.25. Among the diseases in which there was a decrease in mortality were the following: The weekly average of deaths from typhoid fever decreased from 13.25 to 6; from whooping-cough, from 4 to 2.5; from epidemic cerebrospinal meningitis, from 4.25 to 2.75; from pulmonary tuberculosis, from 159.5 to 157.25; from diarrheal diseases under five years, from 41.5 to 31.75; from appendicitis and typhilitis, from 10.25 to 9.75; and from puerperal diseases, from 11.75 to 9.25.

HONORS FOR DR. H. M. BIGGS.—The Board of Health recently adopted resolutions complimentary to Dr. H. M. Biggs, on the occasion of his retirement, and appointed him a member of the Medical Advisory Board, honorary general medical officer of the Department of Health, and medical adviser to the Otisville Tuberculosis Sanatorium.

PHYSICAL EXAMINATION OF CHILDREN.—The Health Department reports that in the appropriation for the division of child hygiene for 1913 was included an item of $10,000, to be expended by the division in extending to the child-caring institutions of the city the same system of physical examination of children as was provided for in the public and parochial schools. There are 63 of these institutions in the different boroughs of the city, and five medical inspectors, under the direction of a chief inspector, were assigned to this duty. From March 29 to Oct. 18, 14,697 children were examined, and of these, 6,486 were found to be normal, and 8,211 suffering from one or more physical defects. In general, the proportion of defects noted is about the same as that found among the children in the schools, an exception being noted in the case of defective teeth; owing, without doubt, to the greater attention paid by the institutions to defects of nature. The percentage of defective teeth among the institution children was 38, as against 49% among the children in the public and parochial schools. In October these children were all re-examined to determine whether the treatment provided had had the desired result, and it was found that 2,730, or 44%, were entirely cured; 1,868, or 30%, were improved; and 1,593, or 25%, remained unimproved. Considering the brief period elapsing between the original examination and the re-examination, the proportion of children cured is regarded as remarkable, and indicative of what may be accomplished in safeguarding the health of children when it is possible to apply direct and prompt attention to their needs.

BOTANICAL GARDEN.—At the annual meeting of the managers of the New York Botanical Garden, Bronx Park, on Jan. 12, Dr. W. Gilman Thompson was elected president, to succeed the late Judge Addison Brown. Among the new managers elected was Dr. Lewis Rutherford Morris, and Dr. W. L. Britton was re-elected secretary. Dr. Britton reported that during the past year $116,395 had been received, bringing the total permanent fund of the corporation up to more than $520,000, and that the committee in charge of the work of collection had been instructed to continue its efforts until the fund had reached $1,000,000. The object of the fund is to permit further expansion of the educational and scientific work of the institution, the increase of its collections, and the additional ornamentation of its grounds.

MEDICAL SOCIETY OF THE BRONX.—The borough of the Bronx having been made one of the counties of the State, a county medical society has now been organized to take the place of the Medical Society of the Borough of the Bronx. Dr. N. B. Van Etten, who was recently president of the latter and who is chairman for the borough of the Bronx in the Medical Association of the Greater City of New York, was elected president of the new society.

FISH CANCER.—Dr. H. H. Gaylord of Buffalo, director of the State Institute for the Study of Malignant Diseases, has just made to Governor Glynn the report of a special study which reveals the fact that fish in the State hatcheries, in common with those in most of the other cultural stations where species of the salmon family, including trout, are kept for breeding purposes, are more or less infected with cancerous disease. He has reached the conclusion that what is known as gill disease or endemic goitre is really a malignant growth, and his investigations have convinced him that the affection is caused by a specific micro-organism. It has been successfully transmitted to dogs and rats, but it would appear that he has never succeeded in transplanting the tumors from one fish to another; nor, in his experience, has the disease ever been transmitted directly from infected to healthy specimens. Certain specimens have been found to possess an almost complete resistance to the disease, while spontaneous recovery occurs in a considerable proportion of cases.

1. Cannon's article is a very interesting historical review of this subject.

2. Rosanoff finds that death is the typical termination for patients with senile psychoses, general paresis and cerebral arteriosclerosis, discharge from institutions for alcoholic psychoses, psychoses related to dementia praecox and manic depressive psychoses, and continued residence in the institution for dementia praecox and paranoiac conditions. Of those recovering, the average duration of treatment is about ten months. About 20 per cent. of the cases discharged to self or relatives are readmitted within five years.

3. Mayer describes the tuberculum septi and the anterior portion of the inferior turbinate in either side of the nose as "genital spots" and claims from 50 to 75 per cent. of relief from dysmenorrhea of patients treated with applications of trichloracetic acid to these spots. Applications four times at intervals between menstruation are usually sufficient to obtain lasting results.

4. This report finds that the supposition that the ingestion of good or spoiled maize is the essential cause of pellagra is not supported by study of the conditions. Pellagra is in all probability a specific infectious disease communicable from person to person by means at present unknown. No evidence was discovered to incriminate flies of the genus simulium, except their universal distribution throughout the area studied. If it is distributed by a blood-sucking insect, stomoxys calcitrans would appear to be the most probable carrier. The inclination is to regard intimate association in the household and contamination of food with the excretions of pellagrins as possible modes of distribution of the disease.

11. A foreign-born population of 24.7 per cent. in American cities supplies 44 per cent. of the indigent insane. [E. H. R.]

7. WOODWARD, H. M. M., AND CLARKE, K. B. *Notes on Three Cases of Glanders.*

2. Freyer discusses the symptoms, physical examinations and treatment of cancer of the prostate. He presents eight cases in detail.

3. Morley discusses the etiology and nature of the pericolic membrane first described by J. N. Jackson in 1908 as "a transparent membrane extending from the parietal peritoneum of the right flank across the front of the ascending colon to its inner side and continuous above with the transverse mesocolon." The membrane, according to Jackson, is not an adhesion in any sense. Morley considers that this membrane is congenital in origin and presents six cases which confirm this view. In each of these cases, one as young as five months and another eight years, the nature of the membrane was the same. In addition, in each one of these cases there was a persistence of the ascending mesocolon with resulting abnormal mobility of the cecum and ascending colon. These points Morley discusses as to their embryological origin and as found in monkeys. Unless this membrane causes symptoms it should not be divided.

6. Clark discusses the difficulties in presenting fair and just statistics in tuberculosis work. The paper is short and hardly suited for review but is none the less of distinct importance to all interested in this subject. Among other interesting points the writer suggests that among sanatorium failures should be classified all those who could not be persuaded to go to the sanatorium at an early stage and only applied when a cure was impossible.

1. Cf. *British Med. Journal*, Dec. 20, 1913.

2. This is a good practical discussion of the diagnosis, prognosis and treatment of chorea. Under treatment he discusses diet and medicinal treatment and lays special emphasis on the need of careful supervision when the acute symptoms have subsided.

3. Gwathmey claims the following advantages for oil-ether anesthesia. (1) apprehension is relieved by doing away with an ether cone or mask; (2) no expensive apparatus is required; (3) after-effects are reduced to a minimum; (4) more complete relaxation is secured: (5) the limits of safety are widely extended compared with other methods; (6) a more even plane of surgical anesthesia is anatomically maintained than is possible by the inhalation method. He has demonstrated these preparations in about 100 cases, the ages ranging from 4 to 71 years. He reports in detail on five cases. The method is especially indicated in lung surgery and operations on the head and throat. It is contraindicated in those cases, with the exception of lung cases, in which ether is contraindicated and also in operations on the anus, rectum, etc. He discusses the physiology of this method, which is of great importance to understand clearly. Strength of the ether and oil solution varies from 50% in young children to 75% in adults. One ounce of solution is used for every 20 pounds of body weight. Details of solution, pulmonary medication technic and apparatus are described in the article.

Obituary.

EDWARD CHARLES SPITZKA, M.D.

DR. EDWARD CHARLES SPITZKA, the well-known New York neurologist and alienist, died suddenly on Jan. 13. The immediate cause of death was cerebral apoplexy, but for some time he had been suffering from necrosis of the jaw, of malignant origin, for which he had been operated upon four times. Dr. Spitzka was born in New York City on Nov. 10, 1852, and was graduated from the medical department of New York University in 1873, after which he studied at Leipsic and Vienna for three years. From 1881 to 1884 he was editor of the *American Journal of Neurology*, and in 1885 was appointed professor of medical jurisprudence and neurology in the New York Post-Graduate Medical School. His "Treatise on Insanity" was published in 1883. He was vice-president of the section on neurology at the Ninth International Medical Congress, and at different times served as president of the New York Neurological Society and the American Neurological Association. Dr. Spitzka was especially interested in criminal psychology, and he was one of the scientists selected to witness the first execution by electricity in the State of New York. He was also one of the medical experts in the trial of Guiteau, the assassinator of President Garfield, and he expressed the opinion that the man was insane. His only son is Professor Edward Anthony Spitzka of the Jefferson Medical College, Philadelphia, widely known as an authority on the anatomy of the brain.

Miscellany.

A QUESTION OF VERACITY.

WE quote in full the following letter from Dr. G. W. Crile of Cleveland, published in the Philadelphia *Public Ledger* for Dec. 30, 1913:—

"In your issue of Dec. 19, 1913, is published a letter of Mrs. Henderson, of Washington, D.C., vice-president of the American Anti-Vivisection Society, in which she says:—

"'We eagerly offer our citations in the hope that the public will take the trouble to verify them.'

"I hope the public will take her at her word, for she did not 'take the trouble to verify' her own alleged quotations from my book on 'Surgical Shock.' On page fourteen of this monograph, the following statement is made:—

"'In all cases the animals were anesthetized, usually by the use of ether, occasionally by chloroform, either alone or with ether. In a few cases curare and morphine were used.'

"'I have again gone through the book carefully to discover what possible foundation the writer of the letter could have for her statement that this book 'repeatedly describes experiments followed by the words 'no anesthesia.' I have failed to discover any such words and, therefore, cannot see how her statement can be considered anything but a falsehood.

"As for the book having been withdrawn from public sale, that also is not true. The edition was long ago exhausted and the book is out of print, but it can be consulted at the Library of the Philadelphia College of Physicians and in various private medical libraries."

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR TWO WEEKS ENDING JANUARY 10, 1914.

December 26, P. A. Surgeon J. O. Downy, detached: Bureau Steam Engineering, Navy Department, Washington, D. C., to Atlantic Reserve Fleet.

December 27, Surgeon C. N. Fiske, detached: *Utah* to wait orders.

Surgeon J. M. Brister, detached: *South Carolina* to *Utah*.

Surgeon Allan Stuart, detached: *Vermont* to *South Carolina*.

P. A. Surgeon W. L. Mann, detached: Naval Recruiting Station, Dallas, Texas, to Training Station, San Francisco, Cal.

Act. Asst. Surgeon J. B. Bostick, detached: Training Station, San Francisco, Cal., to Recruiting Station, Dallas, Texas.

December 30, Surgeon H. W. Smith, Naval Hospital, Boston, Mass.

January 3, 1914, P. A. Surgeon H. A. Giltner, detached: Naval Dispensary, Norfolk, Va., to Hospital at that place.

P. A. Surgeon W. Chambers, detached: Naval Hospital, Norfolk, Va., to Dispensary at that place.

January 5, Surgeon J. F. Murphy, detached: *Idaho* to *Montana*.

P. A. Surgeon F. H. Brooks, detached: *Birmingham* to wait orders.

P. A. Surgeon D. G. Sutton: *Birmingham* to *Montana*.

January 6, P. A. Surgeon C. F. Cottle, detached: Training Station, Great Lakes, Ill., *Mississippi*.

January 7, P. A. Surgeon A. H. Dodge, detached: *Mississippi* to *Idaho*.

January 8, P. A. Surgeon C. B. Munger, detached: *California* to waiting orders.

Surgeon J. A. Murphy, detached: Naval Training Station, San Francisco, Cal., to Atlantic Reserve Fleet.

Surgeon R. R. Richardson, detached; *New Jersey* to waiting orders.

P. A. Surgeon W. H. Cole, Detached: Naval Hospital, Mare Island, Cal., to *California*.

Asst. Surgeon J. V. Howard, detached: *Quiros* to Canacao Hospital, P. I.

Asst. Surgeon C. L. Beeching, detached: *Rainbow* to *Quiros*.

SOCIETY NOTICES.

THE HARVEY SOCIETY.—The seventh lecture will be delivered on Saturday, Jan. 24, at 8.30 p.m., at the New York Academy of Medicine, 17 West 43d Street, by Prof. Sven G. Hedin, University of Upsala.

Subject, "Colloidal Reactions and Their Relations to Biology.

THE NORFOLK DISTRICT MEDICAL SOCIETY.—A regular meeting of the Society will be held at Masonic Temple, 171 Warren Street, Roxbury, Tuesday, Jan. 27, at 8 p.m. sharp.

Business.

Communications.

"Medical Inspection of Immigrants at the Port of Boston," A. J. Nute, M.D., Acting Assistant Surgeon, P.H.S.; H. B. C. Riemer, M.D., Acting Assistant Surgeon, P.H.S.

The February meeting will consist of an illustrated talk on "The Identification of Prisoners," by Mr. Gustaf Gustafson, of the Secret Service.

The March meeting will be held at the Psychopathic Hospital. In addition to the papers a clinic will be held.

Annual meeting May 12, American House. The Censors will meet May 14th for the examination of candidates.

BRADFORD KENT, M.D., *Secretary*,
798 Blue Hill Avenue, Dorchester.

Refreshments after the meeting.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—The annual meeting of the Society will be held in Sprague Hall, Medical Library Building, on Monday, January 26, 1914, at 8.15 P.M.

Address: "The Ninth International Otological Congress," Dr. Clarence J. Blake.

The annual business meeting will be held at 9 P.M.

Supper will be served at the close of the meeting.

E. W. TAYLOR, M.D., *President*.
ROBERT M. GREEN, M.D., *Secretary*.

THE BOSTON SOCIETY OF MEDICAL SCIENCES.—The next meeting will be held on Tuesday evening, January 27, 1914, in the amphitheater of the Peter Bent Brigham Hospital, at 8.15 o'clock.

Program:—

Exhibition of cases.

Dr. E. Goetsch, "Remarks on the Cytological Characteristics of Different Functional Conditions."

Dr. A. F. Lugar, "Spastic Conditions of the Stomach."

THOMAS ORDWAY, *Secretary and Treasurer*,
Harvard Medical School.

APPOINTMENTS.

BOSTON DISPENSARY.

DR. PAUL J. D. HALEY, Assistant to the Surgeons in the Eye Department.

DR. BENJAMIN F. MURRAY, Assistant to the Surgeons in the Ear Department.

DR. E. W. FISKE, Assistant to the Surgeons in the Orthopedic Department.

DR. ANDREW R. MACAUSLAND, Assistant to the Surgeons in the Orthopedic Department.

DR. AUGUSTUS RILEY, Assistant to the Surgeons in the Genito-Urinary.

DR. FREDERICK L. KELLOGG, Assistant to the Physicians in the General Medical Department.

DR. JOHN T. WILLIAMS, Assistant to the Surgeons in the Gynecological Department.

RECENT DEATHS.

DR. MAX DANTES of New York died on January 8, at the age of 41. He was graduated from Bellevue Hospital Medical College in 1893.

DR. EDWARD CHARLES SPITZKA died of cerebral hemorrhage on Jan. 13 in New York in his sixty-third year.

Original Articles.

RECURRENCES OF ULCER OF THE DUODENUM FOLLOWING OPERATION.

BY WILLIAM J. MAYO, M.D., ROCHESTER, MINN.

IN an investigation of the results following operation on 600 cases of ulcer of the stomach and duodenum in which the history subsequent to the operation was ascertained, Graham[1] found that 81% were so relieved as to be considered cured and 10% were markedly benefited, that is, 91% were cured or improved, and 5% of the remainder were moderately improved. The results in the gastric group were not as good as in the duodenal by 3 or 4%. In a small number of the cases there was a recurrence of the symptoms following relief of some weeks or months; a small number of such have been re-operated on in our clinic. Also a small number in which the primary operation had been done elsewhere were re-operated on here. A study of the findings at the second operation has proved both interesting and suggestive, and it is my purpose to discuss the recurrence of symptoms following operation for duodenal ulcer on the basis of this data.

Gastrojejunostomy was the method of choice in the larger number of cases of duodenal ulcers subjected to operation. If actual obstruction existed to the third and fourth degrees, gastrojejunostomy, when properly performed, gave almost certain relief. Plummer[2] points out that such mathematical estimation is much more definite than the use of the terms "marked," "moderate," "considerable," etc., which have only relative meaning, and in estimating degrees of obstruction he advises the use of mathematical equivalents of descriptive terms. For example, obstructions are divided into four groups (1) represents those slighter degrees which might or might not be found on different occasions, (2) represents particles of food regularly found later than the normal period, (3) a grade of obstruction which retains certain parts of the food but allows the bulk of it to pass, (4) retention from mechanical causes which would result in the necessity for removal of such products by the stomach-tube or by vomiting. In response to mechanical obstruction, the stomach acts much like the heart, having periods of dilatation with feeble muscular action in which food remnants are found, and at other times good compensation when such remnants are not found. Obstruction to the first degree may be temporary, occasionally taking place as the result of pyloric spasm, which in turn might be caused by any one of a large number of diseases. Obstruction to the first and second degrees, if they are due to mechanical causes, will ordinarily be relieved by gastrojejunostomy, but not so surely as those accompanied by more marked obstruction as occurs in groups (3) and (4). The greater the obstruction within limits the better the results of gastrojejunostomy and the converse holds equally true that those cases with slight obstruction or without obstruction furnish the highest number of failures to cure.

Failure to cure and recurrences following operation can be divided into two general groups: First, failure of the operation to relieve the stomach of its acid, irritating secretions and inadequate protection of the ulcer itself during the healing period. This condition occurs more often in those cases without obstruction or with obstruction to the first degree in which gastrojejunostomy has been done, especially in the well-nourished individual without obstruction. The pylorus is open and much of the food passes out of the pyloric orifice in preference to the gastrojejunostomy. In such cases, attempts have been made to close the pylorus, thus forcing the food out of the gastrojejunostomy opening. Such closure of the pylorus may be brought about simply by infolding the pyloric end of the stomach with buried silk sutures. Fowler[3] used silver wire for this purpose. Lambotte[4] passes a piece of twine about the stomach just above the pylorus, ties it tight enough to mechanically obstruct, but without sufficient tension to interfere with the circulation, which would result in casting the ligature into the lumen of the organ. In radiograms following the bismuth meal Lambotte[4] has shown the pylorus blocked years after such closure. The general experience has been, however, that closure by the use of sutures has not produced a permanent blockage, but that these sutures are eventually passed into the lumen of the stomach with restoration of the channel, a result which rather regularly takes place in experiments with the normal stomachs of dogs, cats, etc. To obviate this, Wilms[5] introduced the practice of removing a piece of living tissue, *i.e.* a strip of the sheath of the rectus abdominus muscle one-half inch wide and four or five inches in length, which was drawn twice around the pyloric end of the stomach, pulled sufficiently tight and fastened, acting as a living obstruction. This has also been done using a strip of omentum.[6] For some time the method introduced in our clinic by C. H. Mayo has been practiced in such cases, that is, cutting a strip from the gastro-hepatic or gastro-colic omentum, leaving it attached at one end and drawing it twice about the stomach just above the pylorus, or, if the ulcer of the duodenum is sufficiently far below the pylorus, the omental strip is passed about the duodenum below the pylorus between it and the ulcer. The site of blocking should be diminished in size by the application of several interrupted sutures of fine silk to take the strain during the healing process. Since we have used this procedure the blockage remains permanent so far as we have been able to ascertain. However, sufficient time has not elapsed to show its exact

value, but it is undoubtedly true that living tissue drawn about the pylorus is more permanent than mechanical devices in which foreign bodies, such as threads, are used. Recently I re-operated on a case in which the pylorus had been closed in this manner for something more than a year. The strip of living tissue was still in place and covered with adhesions and the pylorus was securely blocked. Von Eiselsberg[7] divides the pyloric end of the stomach and closes both ends. This method is sure, but with a definite although small mortality. Haberer[8] advocates the unilateral exclusion of the pylorus (von Eiselsberg) in all ulcers of the pylorus and duodenum, not only because of the certainty of preventing food and gastric secretion from passing into the ulcerated area, but also because it prevents pyloric spasm and traction on the adhesions. In some instances, this latter condition is the cause of much pain and distress. While the unilateral exclusion has not been used in our clinic as a primary operation, it has been found very successful as a secondary procedure for the relief of pain, of recurring hemorrhage, or recurrence of the ulcer-syndrome in patients on whom a gastrojejunostomy has been made, which was mechanically successful, but in which some of the above symptoms continued. For several years it has been our practice in duodenal ulcer without obstruction and in which the conditions were favorable, to remove the ulcer from the duodenum by excision if possible. In our early cases the ulcer alone was excised. A considerable percentage of the cases subjected to simple excision relapsed within a year and it then developed that in addition to the excision it was necessary to do some type of drainage operation, either gastrojejunostomy, or a plastic on the pylorus, preferably the gastroduodenostomy of Finney[10]. The Finney operation lends itself admirably to excision of ulcers of the duodenum, the ulcer, being drawn directly into the operative field as the sutures are placed, can be excised with great ease and safety. Following gastrojejunostomy, if obstruction to the first and second degree exists, the ulcer should be infolded, as suggested by Moynihan,[11] and the pylorus blocked by living tissue. Especially should this be done if no obstruction, potential or actual, exists. If obstruction to the third and fourth degree be present, nothing more than gastrojejunostomy is essential, although infolding the ulcer is advisable. When hemorrhages were noted in the histories of the patients, the regional blood vessels were caught by sutures and tied.

In the second group of cases recurrence of the ulcer following gastrojejunostomy was apparent rather than real, and had its origin in improper suturing in the gastrojejunostomy. This happened in some cases which were most favorable for gastrojejunostomy, even when obstruction to the third or fourth degree existed at the time of the primary operation. Secondary operation showed that there was no recurrence of the original ulcer, but that a new ulcer had formed at the site where the gastrojejunostomy was made, due to heavy silk or linen sutures hanging in the suture line. Radiograms following a bismuth meal before re-operation showed that the gastrojejunostomy was not working well and that food was delayed in passing out of the stomach. The acidity of the gastric secretions in these cases was high and the retention of secretions on an empty stomach, as shown by the stomach-tube, indicated a high degree of hypersecretion, in fact, the whole ulcer-syndrome had re-developed to such an extent that recurrence of the original ulcer seemed certain.

In a previous paper[12] I reported cases of gastrojejunal ulcer secondary to gastrojejunostomy due to defects in the operation itself and especially suture ulceration. Further experience has confirmed the views then expressed. The length of time these sutures will hang in the suture line is remarkable; one case as long as 22 months after the original operation. Eight cases of this description, in five of which the original gastrojejunostomy was performed in our clinic, were re-operated on. In two (one of our own) there were intercommunicating fistulas between the stomach, jejunum and transverse colon. Both of these patients had feculent material in the stomach. The finding of colon contents in the stomach following gastrojejunostomy is an indication of perforating gastrojejunal ulcer into the transverse colon. In a third case an abscess was found connecting a perforation of such an ulcer to the abdominal wall. In five of the cases re-operation showed a heavy strand of silk or linen hanging in the wound, and I have reason to believe that this was the original cause of the gastrojejunal ulcers in the others. In two cases, the condition of the tissues were such that after removal of these heavy ulcerating sutures it was thought wise to cut away the gastrojejunostomy, completely restoring the wall of the stomach and jejunum by suture and then doing a plastic operation on the pylorus. This procedure proved so difficult that in later cases the gastrojejunostomy was reopened in the suture line and the suture extracted. The opening was then enlarged by a plastic operation, using interrupted sutures for the purpose. Experiences of this kind teach that very fine silk, not heavier than 0, should be used for gastrojejunostomy, that the bite of the sutures should be as near the margin of the incision as possible and that, if it is necessary to reinforce a weak suture line, interrupted fine silk sutures are advisable or such sutures used for part or the whole of the outer row. It has been our practice for a long time to use catgut for the inner row, but it is not the inner row that gives trouble. It is the outer or musculo-peritoneal suture, and I have no doubt that if the order were reversed, using silk or linen for the inner row and catgut for the outer, better results would follow. How-

ever, catgut is so good a culture medium that one hesitates to use it on the peritoneal surface of a necessarily infected wound.

If the margins of the opening in the transverse mesocolon contain fatty tissue, it should be sutured to the stomach rather than to the gastrojejunal suture line. Otherwise, it may form a collar-like mass constricting the opening.[12]

The gastrojejunal opening, as a rule, should be placed at a point directly under the cardiac orifice and not in the pyloric end. The point to be selected has its origin on the lesser curvature a little to the right of the incisura angularis and passes vertical oblique to the left. Two cases of contracture of a gastrojejunostomy made in the pyloric end close to the pylorus have occurred in our experience; in neither of the cases was the original operation made in our clinic. There were no symptoms of recurrence of the ulcer in these two cases, but only those of interference with drainage from contraction of the opening and in each case the gastrojejunostomy was reduced to small size. In both of the above cases, the gastrojejunostomy was cut off and made at the usual situation with permanent relief. It is evident that an opening made in the muscular pyloric end of the stomach has a greater tendency to contract than when made at the point of election.

PROGRESS IN THE DIAGNOSIS AND TREATMENT OF SYPHILIS.*

BY JOHN H. CUNNINGHAM, JR., M.D., BOSTON.

IF modern thought has any new truths to contribute to the inherited stock of medical wisdom, it is because we are in a position to study more exactly the forces and conditions.

Until within the past few years our knowledge of syphilis has not been of a scientific character; the parasite causing the disease was unknown and the personal equation in the establishment of the diagnosis was too often an important factor in the recognition of this disease, and treatment was conducted in a most arbitrary and unreliable manner. We did possess much inherited knowledge in regard to this disease based upon physical observation; the opportunity for which has been great, syphilis being one of the most universal diseases, and no organ in the body being exempt from its effects.

Syphilis has been recognized by the modern world since about 1494, at which time it appeared among the soldiers in the army of Charles VIII, then King of France. It spread rapidly over Europe and has become one of the common diseases in all civilized countries. The weight of evidence seems to be that the disease was introduced into civilization by Christopher Columbus's men, and that it was acquired by them on the Island of Hayti.

Syphilis, gonorrhea, and chancroid were considered as the same disease until about 100 years ago, when Phillippe Ricord proved that syphilis and gonorrhea were distinct diseases and established the theory for primary, secondary and tertiary syphilis. The discovery of the gonococcus by Neisser and Bassereau's work, differentiating true chancre from chancroid, established these three diseases as distinct, and from that time they have been clearly separated. Since syphilis has been considered as an entity observations have established the facts that syphilis is an infectious disease, acquired by contagion or heredity, chronic in its cause, intermittent in its character, and may involve any structure of the body. We have inherited the knowledge that the acquired disease begins as in the eroded, indurated papule, at the point of inoculation, within a few weeks (usually three) after contact with the virus, the lesion being known as the chancre, and that accompanying the chancre there are associated changes in the adjacent lymph nodes, characteristic inasmuch as they are small, shotty, hard and discrete, except when the chancre is secondarily infected with pyogenic organism. We have the knowledge that within a few weeks following the appearance of the chancre (usually six) there is a general infection manifested by characteristic exanthemata, upon the skin and mucous membrane, a characteristic general glandular involvement, and perhaps an iritis or a periostitis. We have been aware that after all symptoms and lesions have disappeared, that the disease may again manifest itself in a variety of forms which we have termed tertiary lesions, and that a group of symptoms may appear which are really syphilitic in origin but which may not be clearly correlated with syphilis and are termed the parasyphilides, as, for example, tabes and general paralysis.

We have been well informed that a child born of syphilitic parents may inherit the disease, and that the disease may manifest itself in one way or another at any period of subsequent life, and that the majority of miscarriages are due to infection by this disease. Also that the disease may remain latent in the offspring of syphilitic

* Read before the Worcester District Medical Society, Nov. 12, 1913.

parents and manifest itself in future generations.

All medical men have been aware of these general facts relative to the disease for many years; also that the lesions of this disease may usually be controlled by mercury and by the iodides. Clinical experience has proven it advisable to continue the administration of these drugs for many months after the secession of all symptoms in an attempt to prevent a reappearance of the lesions which experience has likewise taught us to anticipate. We know that the reappearance of lesions and the development of the parasyphilides in those considered well treated has left us without any certainty as to the effectiveness of our treatment. And so we have been aware for years that our inherited knowledge has not given us in this disease all that we have had in many other diseases.

New facts of primary importance have developed, which new truths added to our inherited stock of knowledge furnishes us with an intelligent foundation for the treatment of this disease equalled by few and surpassed by none.

The investigations as to the etiological factors in the causation of syphilis, which have been conducted for years, terminated with the discovery of the Treponema pallidum or Spirochaeta pallida by Schaudinn and Hoffman in 1905. The importance of this discovery and the subsequent work proving the Treponema pallidum to be the etiological factor of syphilis has been great. As a direct result of this discovery we were given within two years the Wassermann test, which no longer leaves the diagnosis of syphilis in doubt, and makes the treatment of this disease no longer a matter of guess work. The establishment of the fact that syphilis was due to a spirillosis led Ehrlich, who was studying the effect of arsenic preparations on animals infected with different spirilla, to apply his new principle of chemotherapy to animals infected with the spirilla of syphilis and later to syphilis in the human. So it has come about since 1905 that we have learned to recognize the parasite of this widespread and important disease; to have been given a sero-diagnostic test which establishes the presence or absence of the disease in doubtful cases; and a new therapeutic measure which controls the disease far better than any measure heretofore known.

This remarkable sequence of scientific events following rapidly upon one another has aroused an unusual interest in the minds of the medical profession of the world, and has engaged the thought of the laity in one of the most important diseases to which the human race is heir. Before this interest was aroused among the medical profession syphilis often escaped detection in its later stages, and in the early stages the diagnosis depended mainly upon the development of the secondary rash, or in other words, waiting until the individual gave evidence of the general infection before treatment was begun. The old teaching that treatment should not be instituted until the diagnosis was established remains true today, but the diagnosis may be made earlier and treatment begun before the system is saturated with the virus of the infecting organisms. This is brought about by finding the spirochaeta in the earliest of all lesions, the chancre. The finding of the organism in the chancre establishes the diagnosis and indicates that treatment should be instituted at once, and with the new form of treatment it is often possible to prevent the general infection from progressing to the point of producing general manifestations, or in other words, checking or aborting the disease without the appearance of the usual secondary signs. The spirochaeta pallida is also found in mucous patches, and its demonstration in such lesions, especially when mucous patches are the only questionable lesions present, makes clear what was previously often confusing; doubt arising whether the disturbances on the mucous membrane were due to the disease, mercurial treatment, or other affections, such, for example, as leucoplacia. The organism can also be demonstrated in the papules of the secondary eruption and in the lymph nodes, which, however, from a diagnostic standpoint, is seldom important; but their demonstration in tertiary lesions, such as ulcerations, and in condylomata furnishes evidence that the disease is communicable through lesions of this nature. It is of scientific interest to know that the parasites may be found in nearly all of the tissues of the syphilitic fetus, even the bones, and also in the placenta and cord.

While the diagnosis of syphilis may be made by demonstrating the organism in any open lesion of syphilis, the chancre, mucous patches, ulcerations and condylomata, the patient is not always observed with these clinical manifestations of the disease, but without demonstrable lesions other than a general glandular enlargement, and even this may escape detection. In the event of a suspicion of syphilis being entertained by a questionable history, or indefinite and not absolutely characteristic symptoms, such as nocturnal headaches, rheumatism, and pain in the long bones, tumor masses which might be gummata, or nerve disturbances of nearly any variety, we must have recourse to the Wassermann reaction as applied to the blood or the spinal fluid to aid us in the diagnosis. As far as the diagnosis is concerned, therefore, we now have little excuse for not recognizing syphilis in the early or late forms. In the primary stage we are not to wait until the secondary eruption appears to begin treatment, but should demonstrate the organism in the chancre, or establish the diagnosis by a Wassermann reaction, which is sometimes, but not always present before the eruption appears. In the later stages the organism may be demonstrated in all open lesions, and a positive Wassermann reaction may be considered evidence of the disease. In the spinal cord affections fluid obtained from the spinal canal by lumbar puncture for a Wassermann

test is indicated in order that the diseased condition of the cord may be decided as syphilitic or otherwise.

The demonstration of the spirochaeta is not difficult and any practitioner who is capable of making an examination of urinary sediment is capable of recognizing the spirillum of syphilis. The technic is simple, the parasite being detectable in the living state by the dark field illuminator, or in dry smears by staining with different reagents. The dark field illuminator is a rapid and effective method of diagnosis, and one may observe the organisms in a living state, noting their movements and manner of reproduction, but its use must be limited as it is a special and expensive equipment.

The detection of the parasite in smears is simple, quite as satisfactory for practical purposes of diagnosis and may be carried out by the practitioner in his office, without special apparatus or devices. The preparation is made as follows: The lesion from which the smear is to be made is cleaned with water or soap and water, if necessary to remove crusts, pus, or any coagulated masses, from the real surface of the ulceration. With gauze or a small curet the lesion should be curetted at a point where the sound and ulcerated tissue approximate one another, that is, at the margin of the ulceration. Bleeding will result, and as only serum is desired for the smear, the blood is wiped away, and the curetted area is compressed firmly with gauze until the hemorrhage is checked. With the removal of the compression, a flow of serum will take place. One or two drops of this is collected by a sterilized platinum loop, and placed on a slide. Many different methods of staining have been tried, the Giemsa stain, essentially an analin stain, was the one originally employed by Schaudinn and Hoffman, but cannot be recommended for practical purposes of diagnosis, as it requires from 18 to 24 hours to complete. To those interested in the various methods of staining the parasite, this method and that of Schereschewsky, the method of Romanowski, Hastings' stain, and Stearns' silver method, will all be found satisfactory, but, as it is my desire to make the method of detecting the parasite one of simplicity and for practical purposes only, I will describe the method of staining with India ink. This method, first brought forth by Burri in 1909, and later proven to be accurate by Hecht and Wilenko and by Fruehwald, Cohen and others, consists of placing a loopful of the serum on an absolutely clean slide (washed with soap and water, placed in alcohol for one minute, and dried by passing through a flame), and mixing with one loopful of commercial India ink. After mixing these two fluids, spread the mixture over the slide by drawing the edge of another clean slide over the first, as in making a blood smear. The film dries in less than a minute without heat, and is then dark brown or black in color. Nothing further is necessary except to apply to the film a drop of oil and to make the examination with an oil immersion lens. The field is observed as a homogeneous black or brown color, with the blood cells, extraneous matter and spirochaetae shining through as colorless refractal bodies. The spirochaetae are readily differentiated from anything else. They appear as an extremely slender refractile thread from 7 to 21 microns long, which is from one to three times the diameter of a red blood corpuscle, closely wound in a corkscrew form, the windings being absolutely regular, and from 5 to 20 in number. There is one spirochaeta which often appears in the smears together with the spirochaeta pallida, the spirochaeta refringens. This spirochaeta, which grows on the surface of ulcerations, has no points in common with the spirochaeta pallida. It is much thicker, has but four or five convolutions, which are more drawn out and wavy. In making smears from questionable ulcerations in the mouth, the spirochaetae buccalis and dentata may appear in the smear; it cannot be confused with the spirochaeta pallida because they are both thick spirilla with relatively few convolutions, and never have the closely wound corkscrew form of the spirochaeta pallida. There is only one other spirillum which requires mention, which is known as Vincent's spirillum. This resembles closely the spirochaeta refringens, and always is associated with a fusiform bacillus.

Just a word about the India ink for use in this method of staining. The best kind is Chinchin, made by Gunther and Wagner. Barach criticized the India ink method on the ground that India ink might contain bodies resembling spirochaetae, but this does not apply to the ink referred to above, and as Cohen and others have pointed out, is referable especially to Higgins' India ink. So much for the establishment of the diagnosis by demonstrating the infecting organism in syphilitic lesions. We will next consider the newer method of diagnosis of the disease after general infection has taken place.

Without describing the technic of performing the Wassermann reaction, which is distinctly a technical procedure, only to be carried out by trained laboratory workers to be reliable, I desire to speak of how the test is of practical value to the practitioner as an aid in diagnosis.

One is only required to know certain things to avail himself of the valuable information furnished by the Wassermann and allied tests. In the first place, the Wassermann reaction may not take place in the individual before the secondary eruption appears. I have repeatedly found it negative three weeks after the appearance of the chancre, but have frequently found it positive five weeks after the appearance of the primary sore, but even at this date it may be negative. At this stage of the disease the demonstration of the spirochaeta pallida is the more reliable evidence in establishing the diagnosis. The Wassermann test should never be expected to be positive in those under mercurial

treatment, and a period of at least four weeks, and better six to eight weeks, absence from mercury should elapse before a negative Wassermann finding may be considered reliable. It is a well established fact that mercury renders the Wassermann reaction temporarily negative. In the parasyphilitic affection tabes and general paralysis, for example, the Wassermann test as applied to the blood may be negative, while the spinal fluid shows a positive reaction.

As regards the diagnostic importance of the Wassermann reaction, there has been much discussion. All information in regard to this matter, except that expressed by those who have all the facilities and the ability to make correct examinations, is worthless. The tests will, in all probability, remain limited to well equipped laboratories, and to those workers who have made the test a special study.

The Wassermann reaction must be considered a test for a systemic infection, and cannot be expected to be positive before systemic infection takes place. When the unmistakable lesions of syphilis are present, the reaction is only confirmatory evidence in the diagnosis, and of no real diagnostic value after the spirochaetae have been found. The great value of the test is in those conditions where the symptoms suggest a specific causation without sufficient clinical evidence, for example, in the inherited forms of the disease, in the female parent of the syphilitic offspring, cerebral and spinal syphilis, syphilis of the bones and internal organs, gland changes and certain tumor masses. In such conditions much weight must be given to the result of the Wassermann test in establishing the causation as syphilitic or otherwise. A negative Wassermann finding may occur in some syphilities where the spirochaetae are few or encysted in tissue poorly supplied with blood, and repeated examinations at varying intervals are indicated when the lesions continue to excite the suspicion of a specific causation. Repeated examinations are absolutely indicated in all cases treated with salvarsan, for there is a considerable percentage of reactions negative two to three months after such treatment, that will later become positive.

No case of syphilis can be considered intelligently treated except when the Wassermann reaction is employed, as a control to decide whether the case is progressing favorably or unfavorably, and it is the information furnished by this test that enables us to decide when to stop treatment and when we should allow such patients to marry.

The blood for a Wassermann reaction is collected in the following manner. The left arm is bared if the patient is right handed, and vice versa if left handed; an area about the anterior aspect of the elbow joint is made surgically clean by scrubbing with soap and water and alcohol. A rubber tourniquet is lightly applied over the upper part of the biceps, and the fist clinched tightly. The veins thus become prominent unless the tourniquet is so tightly applied as to cut off the arterial circulation. If the arm is particularly fat, the veins may not be visible, and must be located by palpation. A vein being selected, the skin is made tense by the thumb and forefinger of the left hand of the operator, and a 17-gauge needle made sterile by boiling for at least two minutes in an ordinary tablespoon or otherwise, is plunged through the skin by the right hand of the operator, entering the vein in the direction of the course of the vein, with the point of the needle directed upward toward the shoulder. The blood is collected in a test tube, which may be made sterile by boiling, or as I prefer, a sterile 10 c.c. pill vial, which may be more easily closed by a tight fitting cork stopper. At least 8 c.c. must be collected and the vial laid on its side at an angle of 45 degrees, so as to allow the serum to separate more readily. The tourniquet is removed, and the puncture covered with a small bit of sterile gauze held in position by a strip of adhesive plaster. This dressing may be removed in eight to ten hours. To obtain the best results, the blood should not be over 24 hours old before testing.

In regard to the new method of treating syphilis much may be said. To put it briefly, the exact place which salvarsan occupies in the treatment of syphilis is not absolutely settled as yet, but there is little question that the disease is best treated by intravenous injections of this drug, alone or combined with any of the various forms of mercury.

The medical literature upon this subject has been most extensive, but after considering much that has been written, one is impressed with the variation in the ideas in regard to methods and results. It is really a difficult matter, even today, to know just where we stand in the rules to be followed in the treatment of syphilis by salvarsan, and statistics for and against the value of this drug serve chiefly to confuse the casual reader of medical literature.

Some authors record series of cases treated by a large initial dose of this drug, followed by two or more comparatively large doses, repeated at various intervals, some a few days, and some, weeks; with or without combined mercury treatment. Others advise small, often-repeated doses, with or without mercury as an adjuvant, while some feel that the best results are obtained by a course of mercury before salvarsan is administered at all. Beside the variations of opinion regarding the most efficacious method to employ, most reports are incomplete, inasmuch as the cases are from hospital or dispensary practice, and disappear altogether with the secession of symptoms, or are not continually observed by one observer, and in most instances the cases are not checked by repeated Wassermann reactions over a sufficient period of time to give us the hard and fast rules to guide us in outlining the best course of treatment to pursue. In other words, there is today no unanimity of opinion in regard to the best manner of conducting the treatment of syphilis by salvarsan.

Nevertheless, even with this confusion of ideas, based upon the variations in the individual ideas of those who have been particularly interested in this subject, certain fundamental deductions may be fairly made. In the first place, the worth of this new drug has been clearly established upon whatever basis it is administered, and it is unquestionable that the intravenous method gives the best results.

There are two important points of caution: The drug must be prepared according to directions, and asepsis must be absolute in all particulars.

In the past it was felt that patients suffering from circulatory disturbances might not receive the drug without considerable danger. This fear has passed out of my mind, for I have often given the drug to patients suffering from almost all forms of circulatory disturbances, but in all such individuals with high blood pressure, considerable blood has been drawn off before the injection was made. I have given the drug several times to patients with diabetes, and improvement rather than otherwise has taken place in those suffering from diseases of the optic nerve, the disease in these cases usually being syphilitic in character. One patient, a doctor, who was absolutely blind, received five large doses of the drug (three of .9 gms. and two of .6 gms.) with the result that the eyesight is now such that he can read and walk about the city streets without assistance. While it may not be important to bleed patients with high blood pressure at the time of making the injection, there can be no harm in so doing, and the fear of serious effects which might be caused by increasing the intravascular pressure in such individuals is minimized.

I have never in my own experience observed any permanent untoward effects from the use of this drug. In two early cases some of the drug infiltrated the subcutaneous tissue. In both of these patients, and in others that I have observed, occurring in the practice of other men, there was a slow necrosis of subcutaneous tissue and fascia, resulting in a very slow sloughing and repair process. I am familiar with two cases of death following general sepsis depending upon faulty and unclean technic. One of these patients had a septic meningitis. I believe there are unquestionably many serious results depending upon faulty technic, of which we are unfamiliar because no mention is made of them. It may be fairly said, however, that those who have given this form of treatment careful attention may carry out this new treatment with safety. As I have repeatedly said, however, this treatment should not be employed by any one who has not first seen the details of its administration, and who cannot for whatever reason carry out the details absolutely.

Beginning in November, 1910, while the drug was considered by Ehrlich as in the experimental stage, I have continued to employ it in nearly every case of syphilis which has come under my care, both in private and charity clinics. My observations are similar to those made by others who have had much experience with the treatment of this disease by salvarsan, both in regard to the impossibility of curing all syphilitics by a single dose of the drug, and the advisability and necessity of sometimes combining mercury with this new remedy in an attempt to free the individual of the infecting parasite. Indeed, it has occasionally been impossible, after repeated injections of salvarsan and energetic mercury treatment, to prevent the recurrence of a positive Wassermann reaction. I have repeatedly, in fact usually, seen all visible lesions of the disease rapidly disappear with a single dose of the drug, which was responsible more than anything else for the early belief that a single dose of this new drug resulted in a cure. The period of time that this belief could be reasonably entertained was of short duration, for the lesions often recurred, a negative Wassermann reaction was not always found even in the absence of all symptoms, and even repeated negative Wassermann reactions at intervals of months after the administration of the drug sometimes again became positive without recurring symptoms. On the other hand, I have under observation many patients in which a single dose of the drug has apparently destroyed all the parasites and repeated negative Wassermann reactions and absence of clinical signs must lead to the belief that these patients have been cured. I think that it is a fair assumption that patients who have gone two years with repeated negative tests and no clinical symptoms, may be considered cured, and I have had two patients again acquire the disease, which is to my mind the best proof of the truth of these conclusions.

It was to take care of the cases in which lesions recurred and a Wassermann reaction either remained positive or becoming negative, again became positive, that the hope of a cure in all cases by a single dose were lost, and that treatment was energetically pushed beyond the ordinary clinical and laboratory requirements by rapid repetition of injections of salvarsan, with or without mercury, in order to do too much rather than too little. How much relapses have been favorably circumvented by such energetic measures is not certain by any means, for it is well known that even under this "gunshot" method, that a recurrence and a positive Wassermann reaction and recurrence of lesions is not materially changed by such a procedure. It is impossible to accurately determine the percentage of cases benefited by over-treatment as compared with those who are treated in a more conservative manner. It is felt by certain observers that if one or two closely repeated doses of salvarsan failed to effect the desired result, that many closely repeated injections failed also. So it is in this confusion of methods that it is impossible to give to the practitioner any pre-

cise course to pursue with promise of a definite cure for his patient.

Disregarding statistics and the diverse opinions of others and considering the subject from the viewpoint of personal observation based upon a considerable experience, I have come to certain definite conclusions, the most important of which is that syphilitic patients must continue now, as in early days, to remain under observation for years.

It is urged that a conservative policy be pursued until the future offers a solution of this confusion of opinions, and for the reason that it is more prudent at this time to rely upon clinical signs and laboratory control than to impose a haphazard, hit-or-miss and most miscellaneous form of treatment, which is a tremendous inconvenience to the patient while promise of distinct advantages cannot be offered.

THE CASE FOR RADIUM THERAPY.

BY SAMUEL DELANO, M.D., BOSTON.

Of an American status we may scarcely speak. In comparison with the activity in foreign lands our interest deserves but slight mention.* This state of things is, however, by no means creditable. In so far as it is conditioned upon the expenditure involved or the inability to obtain material, it may be condoned, but as an expression of nonchalance it is by no means so easily defended. Radium has already a past and has been recording history at a rapid rate, especially within the last year. Radium therapy is then a plant of too vigorous a growth to be sniffed at. America ought to raise some plants of its own!

It is true that the pathway of medicine is strewn with those overthrown pillars which once were thought to mark milestones on the highway of progress, but which proved only *wegweiser* into a *cul-de-sac;* but that should be only a stimulus to a finer discernment, not to an *insouciance.* Radium has to encounter a good deal of the *nil admirari* attitude—a certain assumed aloofness of the "you can't feaze me" character; but nowhere could this be less justified than in the case of radium.

In the first place this attitude is not true skepticism, which in its real significance implies a broad and elevated outlook (*Skopein,* to overlook from a height). In this sense, skepsis in medicine is really the handmaid of truth. The surgery of today might, for example, with good advantage concern itself as much with skepsis as with sepsis. And so of radium: we may, if you will, look upon it as still in an experimental stage, even to a considerable extent in the "*quod sit demonstrandum*" state, but even in the event of ultimate failure and disappointment, America ought to take part in so huge a therapeutic enterprise, if only for the sake of saying "*quorum pars fui.*"

Few new therapeutic measures of two decades have gone further and under better auspices than radium. The large names and towering reputations enlisted in its cause need not be accepted merely on the basis of personal authority. Therapeutic claims are supported by analogous findings in biology and chemistry. A discovery that has jostled the science of physics to its very foundation need not be looked at askance when it threatens to repeat its thaumaturgy along therapeutic lines, nor suspected of affording a mere *appoggiatura* for chicane.

Consider the relation of surgery to cancer. Operation for cancer of the breast, *e.g.* is one of the earliest of surgery, and yet today who shall say that, so far as cure and the lease of life is concerned, cancer of the breast does not remain one of the opprobria of surgery. In order to estimate fairly the results of surgery here, we ought to possess data resting upon a natural history, *i.e.* upon a large series of cases left to themselves and to purely medical treatment. When the question is considered by and large we certainly should have to reckon with the destruction of vital capital effected by surgery.

Here is a woman looking to her friends as well as ever and able to do her work as a singer. She takes a friend into her confidence and reveals a cancer of the breast; at the urging of this friend she is operated on. The whole complexion of things is changed—no recuperation, even under the most favoring circumstances! But on the contrary, immediate prostration and a steady decline to death four months later. Certainly surgery seems an active "precipitant" in such a case. "But," rejoins Surgery, "we must get the cases early." Said a surgeon dying, himself an earnest advocate of much and early operating, "I am sorry I had it done," referring to an operation in regard to which a foremost surgeon had felicitated him on its very early execution.

As to the part performed by surgery even at its best, we may speak merely of "eradication." We may not speak of a "cure" by the knife, as Abbé properly says, but must look to some process along the lines of chemo-therapy which shall be productive of a cell change; and this we seem to have in radium, as we shall presently call to attention; for with radium we may really speak of a *restitutio ad integrum.*

Through quotations let us see of what sound investigators and good surgeons have been able to convince themselves on the relation of radiation to cancer.

Domenichi, while finding radium most useful in superficial cancer, is yet able to report complete clinical cures of deep-seated malignant growths of the parotid neck and uterus with no recurrence in 3-4 years.

Abbé believes "a new era has dawned for surgery."

* This refers to systematic work and does not disparage one whit the distinguished individual efforts of our sappers and miners, Abbe, Williams and Kelly.

He reports that he is meeting with "a never-increasing percentage of success" and that "cancer is not always incurable." Abbé can refer to cures of deep seated giant-celled sarcoma of bone with no recurrence in nine years.

Knox (London Cancer Hospital) believes that in early cases the choice should still be given to operation because we are not as yet certain enough of results in radium, but says that radium "promises an unique field of usefulness in therapeutics."

Pinkus says that radiation has displaced operation, but takes pains to point out that he means only locally speaking—not glands and metastases.

Kroenig, speaking of the pelvis, believes that even operable cancer should be radiated, if it is "controllable by sight or touch."

Bumm and Voigts say in August, 1913, "We are in a position to bring to healing any cancer of any kind, even quick growing, round-celled medullary varieties, in proportion as it can be made accessible—and we can cure the cancer if we can reach the metastases."

Finally Gauss says, speaking of the pelvis, "In Freiburg we do not operate on cancer; we radiate."

Radiation: General Considerations. The activity of radium depends, in the first instance on the formation of the emanation, a gas of definite properties, of which more will be said *infra.* An atom of radium splits into Alpha particles and emanation. In turn the emanation splits (so-called decay) into Alpha particles, and the secondary deposit and from the decay of this last come the two other classes of rays, Beta and Gamma. Now if this splitting or decay occurs in radium that is sealed, the emanation is enmeshed within the radium itself, and the constant decay gives rise to the mechanism of general radiation and the liberation of energy. This is tantamount to ageing of radium, freshly prepared radium being comparatively inert (the maximum of Gamma rays not developing for a month—and there are no Gamma rays until the third decay product in the active deposit,—"Radium C,"—has been reached.

If, on the other hand, the radium is open or dissolved or heated, the emanation is liberated and may be made use of in various forms for internal use. Thus radiation in any case depends upon the emanation, only in the one case, as in a tube, for example, there is a uniform activity of rays from the splitting of the emanation and successive products, while in the other, when emanation is introduced internally, it is in the body that the splitting goes on with the liberation of rays and energy. Thus the use of radium divides roughly, and with due reservation, into external and internal.

Radiation for New Growths. Radiation turns (1) on the quantity and quality of the rays used; (2) on the filter, its nature and density; (3) on the density and composition of irradiated tissue.

1. *Rays* are of three varieties, of well defined characteristics and differences; to them the designations, Alpha, Beta and Gamma have been attached. Alpha rays are not rays at all, properly speaking, but electrically charged (pos.) particles identified with Helium atoms, having a weight of four times that of an atom of hydrogen. They are liberated with an explosive force, and travel at the rate of 12,000 miles per second. The energy of their liberation accounts in good part for the heat of radium, and the force of their bombardment for the immediately superficial injuries (burns, etc.).

The Beta rays are also not rays at all, properly speaking, but a stream of electrons, negatively charged, identified with the Cathode rays (which Crookes originally defined as a "stream of radiant energy") of a mass equal to 1-1700 of a hydrogen atom.

The Gamma rays do not polarize, pass straight by the magnet, are not deflected by the prism; thus they represent waves of ether.

2. *Filtration.* By a filter we mean anything which by interposition may absorb the rays, *i.e.* obstruct their passage. The efficacy of a filter is in proportion to the density of its structure.

Alpha rays, being particles all travelling the same distance at the same rate, would be stopped short by a small obstacle; thus a sheet of paper is sufficient or, in actual use, the epidermis.

Beta rays, on the contrary, show all degrees of penetration and are roughly divided into hard and soft rays.

Gamma rays have been given the name of *surpénétrant* to denote their vastly preponderating degree of penetration.

If you make mere distance the filter, then Alpha rays are cut off by 3.3 cm. of air. Beta by about three times that amount, and on the contrary Gamma rays (as from 1 gm. of radium) would reach a distance of 100 meters and affect the electroscope; or travel 3 + m., penetrate a man and cause fluorescence beyond him. The ratio of penetration of Alpha, Beta and Gamma rays may be expressed by 1:100:10,000.

Simple filters for the Alpha and softer Beta rays are lead paper and rubber tissue or mica. The metals furnish the common filters, however, viz., silver, aluminum, lead, and more recently gold and platinum (half the bulk of lead).

1/20 mm. aluminum screens the soft Beta rays.
1/10 mm. aluminum screens the medium Beta rays.
1 cm. lead screens the hard Beta rays.

Gamma rays need 5 cm. of lead for practically complete absorption though a small fraction will still be left with 10 cm. These figures must be regarded as somewhat flexible.

Thus we see that it is possible to vary the quality of the rays by filtration. But the total rayage may be extraordinarily influenced by filtration. Of the total rayage without filtration

there are 90 Alpha particles to 9 Beta rays and one Gamma ray, but even with thin metallic filtration the figures for Alpha and Beta change places and the Gamma rays may come up to ten. Under strong filtration (5 mm. lead) a total of 600,000 rays is reduced to 5000 (Gamma). One other class of rays there is, viz., "secondary"—created when a metal filter is used. These are called Rayons de Sagnac. They are very irritating, but may be easily screened by a sheet of black paper, 20 sheets of writing paper or 4 mm. of cotton.

3. The third factor in radiation is the density and the composition of the radiated tissue. This is a very important item in the therapeutic use of radiation, because one of the obstacles to greater success has been the comparatively limited localization of its effects. The skin, for example, absorbs two-thirds of the rayage (the negro's skin more). It is thus more difficult to radiate, *e.g.* a gland, through the intact skin (though glands can be absorbed without injury to the skin). Wickham reports, however, a mediastinal tumor improved as to size and alleviation of pressure symptoms.

Wichmann showed that pathological tissue absorbed rays in much greater measure than did normal tissue. Lupus Vulgaris absorbed double in comparison with the neighboring normal skin. It has been calculated that 1 mg. radium will send penetrating rays to a depth of 2 mm. of pathological tissue; with large quantities, 2-2½ cm. of pathological tissue, is the degree of depth usually attained, though influence to a depth of 5 cm. has been observed.

The discharge of Alpha particles has been called the most intense liberation of power in nature. Kinetic energy is their especial characteristic. They account for most of the heat of radium,—their ionization power is such that they have to be screened off in the electroscopic quantitation of radium and their chemical energy evidences itself in catalysis. They must then be irritating and destructive to normal tissue (and to growths perhaps even stimulating); therapeutically they must in the main be rejected.

Soft Beta rays are in much the same category, but the hardest Beta, which are also much more penetrating are analogous in effect on pathological tissue to the Gamma rays. Gauss makes especial use of them and Knox thinks they ought to be more used.

The Gamma rays, however, it is agreed, have the most pronounced therapeutic office. As we have seen, they penetrate a great distance but, their quantity being small, it by no means follows that they will act curatively. The problem is, then, to produce a summation of Gamma rays within a given district. This summation will be a product of intensity (amount of radium), filtration and exposure period. Happy assistance is effected by the use of "cross firing." This refers to the focusing of Gamma radiation from several independent sources and in different diameters, upon a given district.

Gamma rays may easily be shown to have a predilection for cancer cells, especially in proportion to their youth, embryonic character, or developmental state, and under the microscope these may be seen to split nuclei, develop vacuoles and lacunae, and finally to disappear. Furthermore, young connective tissue cells in the neighborhood may be observed developing and multiplying vigorously. Their growth leads to isolation of cancer groups. This is the essence and rationale of the favorable action of radium on morbid tissue. Good tissue elements are stimulated, morbid tissue elements withered and retired.

Resumé of the Results in Radiation. The use of the rays of radium dates from as far back as 1902. At first entirely unmethodical, their employment necessarily could not be productive of substantial results; and it was not until the discovery by Domenichi and the French School that the penetrative Gamma rays far exceeded the others in therapeutic scope and that they could be isolated through means of the thick filter, that the success of today gave promise of achievement.

Much experience by many observers in many thousand cases has set beyond all cavil the marvellous power of radium to demolish growths and conditions of simple and intermediate nature. From warts to non-infiltrating carcinoma, its value has been established as almost infallible. We see exaggerated cell growths blown to smithereens, as it were, by dynamite.

Warts (Abbé) encountered in all situations and of fancy sizes, have been disposed of mostly with one exposure. In ten years he has radiated five hundred cases of epithelioma, superficial cancer and sarcoma "with ever increasing success." He attributes most of his failures to inadequacy of dose or a lame method. Recurrent papilloma of larynx, cousin germane to cancer, he cures with one exposure (100 mgms., 30 min., entirely absorbed in eight weeks), and sarcoma of eyelid (previously x-rayed), disappears with four hours' exposure. Kelly scores a 96% of success in skin growths. Schindler (in a very "meaty" contribution to Radium for October and November (1913) says he has "frequently removed the benign epithelioma of the face (Epithelioma perlée) with an exposure of an hour." And so in angiomata and keloid and rodent ulcer the success has been eclatant.

In skin diseases, especially of the ichthyotic type, psoriasis, lichen, scleroderma, etc.; neuroses with accompanying eruption, eczemas, pruritus, essential or with varying eruptions, radiation has been well tried out and its success is undoubted and substantial. Apart from the question of success, however, radiation has the greatest possible advantage over other means in its notable celerity and simplicity. Its convenience of application alone (it has been called *therapie de poche*) entitles it to decided prefer-

ence, other things being merely equal. One of the most pronounced efforts of the rays may be mentioned as well here as anywhere, viz., its local soothing effect on disturbed nerves. This makes of it almost a specific in the control of an essential or symptomatic pruritus or as an analgesic. Its antipruritic effect of course, makes it extremely satisfactory in relieving an important symptom, while effecting the cure of the underlying lesion. All observers agree as to the extraordinary analgesic effect of radiation. Thus in all neuralgias, especially in sciatica, and in the often terrible pain of new growths, it is capable of rendering remarkable service. An incurable cancer case can be kept comfortable with radiation. The pains of tabes have been relieved in four minutes.

How stands the case between radium and deeper malignant processes? Very much more definitely may we speak than we were in a position to do one year back. The adaptation of those principles which we have spoken of above under the general consideration of rays and radiation, viz., massive doses, heavy filtering and long exposure to the Gamma rays have been productive of results so marvellous that one is not to be blamed for an *a priori* incredulity.

All Europe is aflame. A veritable *radium-fieber* rages. The supply of radio-active material is exhausted and large ready-available funds cannot as yet be expended. All this might be the case with mere hanky-panky on a large scale, but it would be highly improbable. Fortunately the accounts of results leave far less than the usual room for doubt, even from a highly skeptical viewpoint, and it will scarcely do to say in our haste "all men are liars." A highly impressive feature of various reports, as for the pelvic region, *e.g.*, is their striking unanimity. Only here and there is a discordant note. In the face of very enthusiastic accounts by other speakers Nagel rises to say he has gotten no such results. Falk, who denies the specific action of radium, says that after radiating a number of cases of cancer with 50 mgm. radium he never had a complete cure; but in the light of the overwhelming testimony of great surgeons, such as Kramer of Greifswald, Kroenig and Gauss of Freiburg, Doederlein of Munich, and many others, we are justified, at least temporarily, in questioning if methods may not be at the bottom of failures, because so little would make so great a difference in results. Thus Meidner, after being unsuccessful in a number of cases, scores at last a brilliant coup with 30 mgm. radium in a "stinking cancer of cervix." The writer has talked with one man who, voicing disappointment as to his own experience with radium, may be said simply not to have used it.

One of the advances of the past year centres about the coöperation of surgery and radiation. Indeed, there is a good deal of plausibility, not to say cogency, in the view of one operator that radium ought to be in the hands of surgeons and not of radium institutes, towards which the tendency of present fashion veers. Thus we find the London Radium Institute reporting none too favorably on cancer of the rectum, while, on the other hand, Abbé, a seasoned surgeon, with a ten-year experience with radium, is most enthusiastic. The dose should be large, the filter at least 2 mm. lead and the apparatus be left in 8-12 hours at intervals of several days. Kroenig reports a case of large proliferating cancer of rectum cured, with freedom from relapse maintained for six months prior to date of publication.

But consider the importance of method! The radium tube must be placed accurately in the lumen of the stricture within the confines of the tumor—failure to do this is certainly going to result in failure, even perhaps to lead to perforation as a result of injury to sound tissue. So that here again positive evidence carries much further than negative.

The danger of perforation attaches to the radiation of all cancer of the gastro-intestinal tract. Thus Exner of Vienna reports two perforations in twenty cases of esophagus cancer. Schindler has observed one only, and that also in the esophagus, but calls attention to the difficulty of distinguishing from a perforation ascribable to the disease.

Besides the twenty esophagus cases, Exner has radiated forty other deep lying carcinomata in the last ten years. In only two did they remain longer than three years without recurrence, and these two finally showed return in, respectively seven and nine years. This illustrates the necessity of caution in speaking of a cure by radium. (One of the earliest cases radiated—sarcoma of lid—recurred only after ten years). There is a good deal to confirm the hypothesis that the connective tissue, the formation of which is stimulated by the radiation, spreads a net to catch the unabsorbed cancer *reliquiae* and so to prevent metastasis. In sixty deep lying cancers, Exner reports that, with the exception of the two mentioned he could not speak of cure, but of an essential improvement as to local symptoms and duration of life. In cancer of esophagus a preliminary x-raying should be made in order to place the radium within the growth and stricture.

Of cancer of the mouth, esophagus and stomach, Abbé says he is not yet prepared to speak. Of course one obstacle in the way is the inaccessibility of these regions and in consequence, unmanageability of the radiation. Surgery will undoubtedly coöperate in the future as in two recently reported cases of gastric carcinoma, by Julien; a laparotomy was done and the tumors radiated forty-eight hours through the wound by a radium tube enclosed in a catheter—radiation was also continued from the surface. Cures were said to have been obtained.

Cancer of the breast has not been radiated on a large scale, probably on account of the long established prerogative of surgery in the region.

Splendid results, though, have been obtained. Kroenig has in his series a case radiated after laying back a flap of skin—no return at time of writing, nine months after—so a cancer *en cuirasse*, rejected as inoperable, he has cleared up with no return in five months. Abbé reports brilliant results in myeloid tumor of jaw and round celled sarcoma of humerus, with no return in nine years.

But it is more especially in the pelvis that the great advances of the year have been made. By using much larger doses, by heavier filtration, by massing rays, by using a number of packages to serve as a battery, by cross firing, by invoking the aid of surgery to make growths more accessible, by a longer exposure, very remarkable results have been obtained. Kroenig has made the most considerable report with 146 cases (including cancer in eleven regions referred as inoperable from surgeons—in these he is not ready to report except in the eclatant cases cited above).

In 56 cases of inoperable cancer of the uterus 15 were healed so far as good health and histological negation confirmed, the longest absence of recurrence at time of report being 16 months.

If we can do this, why not radiate so-called operable cases—the rate of mortality is large, and, furthermore, classifying them as operable is only to speak surgically, not to guarantee against recurrence. Sixty per cent. recur within the year (when they become inoperable, as a rule, and are considerately passed over to radium). And most of the cases that have been loaned to radium, so to speak, are not only inoperable, but almost untreatable. They stand for the "abomination of desolations." Yet de Courmelles reports out of 100 inoperable cases, 70 improved, with the gain held for from one to four years, and that with only 50 mgms. radium within the uterus twenty-four hours every month. Jacobs of Brussells reports among 120 cases, 24 cases of uterine-wall cancer, all favorably affected. All observers agree as to the great improvement that can be effected in forlorn inoperable cases; their desperate plight can always be relieved by staying the hemorrhage and discharge and by absolutely relieving the pain. Now what might not be the toll of radium if operable cases could be included; many of those of the fundus and parietes are but thin in tissue, a condition that radium might easily influence.

The interrelations of surgery to radiation have been better established in the pelvis than elsewhere. Pre-radiation of a tumor can make a tumor operable by causing the absorption of inflammatory exudate, by creating mobility and accessibility and by removing discrete foci and glands, as in the broad ligament and vagina. Thus Kroenig speaks of making a tumor non-malignant in two weeks. He believes that many operable cases ought to be first radiated, because there is no loss of time. Radiation has dried up the secretion of cancer in three weeks. In five and one-half weeks Kroenig has seen a large cauliflower of the cervix replaced by an normal cervix and only a delicate mark for scar. This case was at time of writing four months free.

So the modern operators go far. They dissect, they bury tubes in the tumor, they radiate before operating, they radiate in the operative wound. Kroenig radiated 64 against recurrence; at time of writing, 20 were still alive with no return, 13 more than a year.

Kroenig has used the most massive doses, even 800 mgms. of radium and mesothorium, sometimes separately, again in combinations with x-ray. He has left in tubes eight days, and he speaks of "Gamma therapy" because of his reliance on Gamma rays solely.

But Bumm begins with a thin filter and the Beta rays, applying very closely to diseased tissues, but protecting healthy with lead—after ten days he uses larger doses and a lead filter. His large dose averages 150-300 mgms.

Other Radiation. Much other radiation has been undertaken and much will be, since dissection and the burying of the tube in the tumor have come into vogue. Thus Turner reports a case of recurrent lympho sarcoma of axilla cured. The tube was buried in the mass and the glands radiated from without; then the glands, having isolated themselves, were dissected. Of this case Prof. Alexis Thompson says, "This was clinically and histologically a round celled sarcoma. Untreated, the duration of life would have been put at three months." Even a tumor of the hypophysis with gigantism has been radiated and benefited.

Domenichi, one of the oldest operators, reports favorably on exophthalmic goitre, using mild radiation and believing the benefit to lie in nerve influence. Turner reports four cases very decidedly influenced; they were inveterate, from two to seven years' duration. Turner thinks his radiation influences blood supply and connective tissue.

Domenichi has radiated the joints of gonorrheal rheumatism, especially small joints, and made brilliant cures, the pain being at once controlled.

In special work a considerable use has been made of radiation. In the eye, many chronic diseases, involving low grade inflammatory conditions, ulcerations, pus formation, catarrhal processes have been cured. A smallish quantity of radium has been used and the tube applied directly to the eye. Enough use has been made of it to show that there is no danger to the mechanism or power of the eye itself. Koster of Leyden reports a clinic in which radiation was used for practically every disease of the eye and surrounding parts.

In the ear there have been recently reported two series of cases of chronic deafness, with or without active processes, the radiation of which was attended by a decided degree of success. A small quantity of radium is applied to the mas-

toid, the external ear and even to the middle ear, all with short exposures.

In the pelvis other diseases than cancer have been freely treated, such as metrorrhagias, metritis, myomata, and great success has been reported by many observers, particularly with smaller fibroids, and when these conditions cluster around the menopause. A moderate amount of radium is used which may be either inserted into the uterus or placed so as to radiate the ovary. Some speak of securing a catamenia precox.

X-ray and Radium. One of the curious facts in the history of radium is that the Gamma rays, which could penetrate a wall or a man or 15 cm. of iron, were thought at first to be of no account. Since then study of them has shown their practical identity with the x-ray. But there are important differences. The softest Gamma ray will penetrate much farther than the hardest x-ray. Lazarus estimates them as 40 times as penetrating.

While the x-ray is an application of artificial radio-activity the radium tube is a "portable Roentgen bulb," *i.e.* there is obviously no comparison between them as a matter of convenience. Again the x-ray is but a single beam, and it takes "many a little to make a mickle"; its action is necessarily very slow if required for much tissue. Compare the method of burying a radium tube in morbid tissue and taking advantage of its uniform radiation in all directions, with the x-ray necessarily having to overcome the resistance of other tissue. The use of heavy filtering is very destructive to the x-ray apparatus. Bumm finds the x-ray "dear and tedious," but expects much from a combination of radium (quick) and x-ray (slow). Albers-Schönburg advises small doses of x-ray and long radiation in myomata, which means for him an eight months' process. Furthermore, great damage has been charged up to the large doses of x-ray that have been used in the last year. Schmidt calls attention to the danger of late effects and damage to inner organs. He has seen persistent diarrhea three months after cessation of raying; also rapid degenerations and perforations.

Injury from Radium. Alpha and soft Beta rays as well as the secondary rays, will all produce an impression on the skin varying from erythema to necrosis; but so well are the laws of screening now understood that it is entirely unnecessary to produce more than a slight erythema, which must be expected when heavy doses and long exposure are used for deep penetrating effects. The sensitiveness of skin varies according to age, old skin being very tolerant. The mucous membranes are more tolerant than the skin. After considerable rayage the skin develops a super-sensitiveness which must later be taken into account by lessening the rayage toward the end of treatment. This acquired supersensitiveness becomes more or less permanent and may be an obstacle in secondary treatment of recurrent neoplasms.

In the course of treating large surfaces, as lupus or a large tumor with long exposure, a condition of apparent sepsis is often observed. The temperature runs high, the patient falls into a condition of lassitude and depression. Knox has observed this in rectal cases.

There have been some perforations of hollow organs reported, some of blood vessels with hemorrhage; but Schindler, on the contrary, says that, by careful management, he has actually cured an involved blood vessel without disturbance.

The scar after radium ought to be almost nil, neither raised nor depressed, and the cosmetic result equally satisfactory,—neither pigmentation, hairs, or telangiectases. That is all a question of proper management.

Finally, radium may blow hot as well as cold, and occasionally stimulate a growth. The reaction of cancer to the radiation varies much, according to the nature of the tissue. More mature cells are more apt to be stimulated. Schindler believes that with smaller doses the Gamma rays for the most part exert their effect in the periphery, while stray rays striking into deeper regions, exert a stimulating effect. He emphasizes the necessity of securing uniform concentration in the whole area under radiation —a condition that is well secured by burying the tube.

Dose. It is often asked with how little radium can one work? Kroenig, as we have intimated, has been working with very high doses, even up to 800 mgms. radio-active material (radium and mesothorium). But Bumm with 500 mgms. and 2 mm. lead filter, reports a lack of toleration even after ten hours' action—fever with bloody tenesmus, an inflammatory exudate, with in one case a sterile abscess. He, therefore, sees no advantage in large doses, but prefers 150-200 mgms. Lazarus warns against small doses, as being stimulating and irritating, and as increasing metastasis, his minimum being thirty mgms. Wickham warns against too much. The case (for cancer) is well summed up by Schindler, who thinks the required amount is adjustable to the effects. If, he says, you have an amount which with continual radiation can destroy a cancer in three to four weeks, you have enough; it being immaterial to his mind whether the effects are attained by smaller (though considerable!) quantities, used through longer periods or a large amount, *e.g.* several hundred mgms. used for correspondingly shorter periods. According to Schindler, several applicators of each about 15 mgms. of "radium element" are sufficient, if they are used continuously day and night.

It will be observed that Schindler uses the term radium "element." This refers to the international standard prepared by Mme. Curie, by which all parcels of so-called radium ought to be reduced to their equivalent in radium ele-

ment. We ought to know first, the amount of radium element in the salt used (strength and kind) and second the square surface, if a flat applicator, or the volume, if a tube. Therefore in the following table it must be borne in mind that we are left in doubt as to the relative quantities of radium element that correspond to the so-called radium.

Small quantities of radium may be profitably used. Thus even Alpha rays, though irritant, may be used where the exposure is to be short, as in superficial epithelioma. So Beta rays may be, as in chronic ezcema, with ten to fifteen minutes' exposure. Varnish applicators give forth a large proportion of Alpha rays and are prone to produce an erythema.

In the distribution to the London Hospitals of the radium purchased with the $50,000 London Express fund, the largest single grant was 250 mgms., but the smallest 15 "with which useful work can be done."

Domenichi radiated his small joints affected with gonorrheal rheumatism with 5-10 mgs. 25% salt.

Results have been secured in:—

Granuloma and trachoma, with 1 mgm.
Scrofulous gland, with 1 mgm. (tube imbedded 23 days).
Ear, with 1-2 mgm.
Uterine hemorrhage, with 4-10 mgm (radiation of ovary).
Lupus and angioma, with 10 mgm.
Goitre, with 10 mgm. (tube imbedded).
Metritris, with 20 mgm.
Fibroids, with 27 mgm. (on uterine sound).
Skin and Cancer, with 20-40 (Wickham).

Mesothorium. Mesothorium (really maesothorium) and its decay products have been favorites in Germany this past year, owing to their relative cheapness. Thorium nitrate is produced from monozite sand for the manufacturing of gas mantles and mesothorium comes from the residue left in preparing the nitrate.

Mesothorium furnishes Beta and Gamma rays, the Alpha rays coming from its radium admixture (often 25%) or from radiothorium, (of the series of decay products). Bulk for bulk, pure mesothorium would be very much more powerful than radium because it disintegrates with 350 times the speed, but by one mgm. mesothorium is meant the amount of mesothorium which shows a Gamma rayage equal to one mgm. of pure radium bromide (standard).

Mesothorium has a half period of but 5.5 years, but its activity varies with age and there is considerable difference in activity of commercial parcels. Its activity increases up to three years, owing to formation of radiothorium. Though in some dispute, the radiation of mesothorium and of radium are generally held to be identical. Czerny prefers mesothorium to radium for superficial lesions; radium to mesothorium for deeper. One observes, however, very much more warning of danger from mesothorium than from radium. Thus Bickel (friendly to it!) recommends caution. Has seen atrophy of normal ovary from 30 mgms., and also late disturbing effects. Bumm says mesothorium is tolerated very well by some, badly by others, and reports injury.

Specific Action of Radium.—Many (as does a user of it in our own city) consider that radium acts as a mere irritant or caustic. But there is an almost conclusive chain of evidence in favor of its action being selective.

1. It can cause the retrogression and modification of cells without inflammatory reaction, or the absorption of an angioma without hemorrhage.

2. It possesses the surpénétrant rays, which can act on deeper tissues without surface reaction.

3. It cures pruritus without irritant action.

4. Its irritant effects show a period of latency—thus the evidence of a burn does not appear for from two to ten days.

5. Parts distant from point of application may be affected.

6. Besides causing the absorption of cells it stimulates fibrous tissue to renew.

7. It leaves no such scar as caustics do—a proper scar after radium is neither raised nor depressed, merely soft, supple tissue in sufficient quantity with no tendency to contract.

8. Radio-activity cannot be checked by any chemical agent. The emanation does not enter into any chemical combination. In this it is entirely different from caustics.

Theory of Radium's Action. Radio-activity is a form of radiation activity which is everywhere present and made use of. Radio-activity has been traced in the body and in gall stones. "Radio-activity in the earth and air furnishes the minimal impulse to the liberation of the normal energy of seed and soil. Small wonder if these ethereal undulations (Gamma rays) are the chosen agents of influence and modification of pathological process" (Butcher). According to Lazarus, Radium therapy is a form of light therapy.

In all nature every increase in life is associated with death. Histological cells like men "rise on the stepping stones of their dead selves to higher things" (Butcher). In radiation, cell death is the basis of therapeusis. *In vitro* a division of leucocytes can be started by adding ereolin or exanthin (chemical products of cell destruction). So, after radiation the dead cells attract phagocytes, which gather as to a feast! Thus the cannibalistic theory of Ross.

The vaccine theory fits in very neatly. By irradiation in one part, distant parts are often affected, as in a widespread psoriasis or acne or widespread carcinoma. Now the vaccine theory would say that the patient prepared an autogenous vaccine, the action of which was general. Thus the radium cure is not dependent on destruction or repair, but represents a biological

recoil, the resentment of the cells to insult, as in the case of bacteria and antibodies. And it must be said that the latency of the burn and its subsequent action in respect to stages and scabs (much resembling cowpox vaccination) lends color to the theory.

To take leave of radium radiation: there is nothing in the above account of its powers and prowess that puts a veto on its claims to have preëmpted a distinct field in therapeutics. Making all allowance for the first flush of enthusiasm and for the jeopardy of human observation, there is no escaping the conclusion that it can lay a healing touch upon varied pathological conditions and that its operations well deserve the motto, *Cito, tute, et jucunde.*

(To be continued.)

A STUDY OF CANCER.

BY SEELYE W. LITTLE, M.D., ROCHESTER, N. Y.

(Continued from page 130.)

Two cases under treatment since this paper was written interestingly confirm this idea. One is a case of cancer of the stomach, bile passages and the pancreas. Two years ago the urine of this patient contained sugar. For a year and a half there has been no glycosuria.

The other is a case of cancer of the rectum. This man had diabetes for several years, with cataract and finally a rectal fistula. A year ago he "recovered" from his diabetes to the elation of his physician. But at about this time his rectal trouble began and he now has an inoperable rectal cancer.

Since observing these cases we have tried without success to obtain a reliable preparation of the islands of Langerhans. As observed elsewhere, there has never been much success derived from the use of a supposedly "aiding" secretion or of a supposedly "antagonistic" secretion in cases of hypo or hyper secretion of another gland. The faulty gland itself must be "aided" by its own kind of secretion or antagonized by partial removal.

Our own experience confirms this. We have had the least success with endodermic cancer where we had to use the "aiding" parathyroid. We certainly desire urgently a reliable active preparation of the islands of Langerhans.

The gastric and intestinal mucosa internal secretion may be eliminated as their function seems to be wholly concerned with the regulation of external secretions, notably the pancreatic juice.

There remain the parathyroids. As to the effects of over-secretion of these organs we know very little, but the condition doubtless sometimes exists. It seems generally agreed that these organs have something to do with calcium metabolism. We do know by painful experience, however, that parathyroids are essential to life, for if removed entirely the individual dies very soon in a condition of tetany. It is interesting to note that experimentally life in parathyroidless animals may be prolonged by the administration of lime salts. For our purpose it is also interesting to recall that if adrenalin be injected into a normal person, sugar promptly appears in the urine. If the parathyroids are absent this sugar effect of adrenalin is enormously increased. And by the way, if the thyroids are absent, glycosuria is almost impossible from the injection of adrenalin. Now in this case we secured the prompt glycosuria of adrenalin injection, so certainly there could not have been a large degree of hypothyroidism, but there might easily have been hypoparathyroidism. Further, such a condition would account satisfactorily for the hyperglycemia of cancer, granting that the suprarenals are normal, for a normal supply of adrenalin would be relatively an oversupply if there existed an undersecretion of parathyroids.

The characteristic results of total failure of parathyroids, namely tetany, suggests another explanation of the hyperglycemia of cancer. We cannot assume, of course, a total failure of the parathyroids, merely a relatively partial failure, so that we should expect an effect on muscle far short of tetany but of the same nature, *i.e.* a too rapid exhaustion of muscle. Exhausted muscle (as in fatigue) calls loudly, perhaps by its waste products, for more adrenalin, which in turn tends to make more sugar appear in the blood. And we know the muscles like to keep a supply of glycogen on hand. We know by experience also that sugar taken by the mouth relieves fatigue. Exhausted muscle calls for sugar. Certainly our experience shows that most cancer patients naturally crave sugar. So the hypoparathyroidism seemed a reasonable theory. It might also partly explain the well-known lassitude existing in the early stages of cancer or even before cancer is suspected.

Therefore the tongue case was started on parathyroid extract gr. 1-20 four times a day. This was Oct. 1. He was told to stop the sugar and the adrenalin. On Oct. 7 pituitrin was added empirically in view of the remarkable effects observed in the skin case. This in spite of the fact that the tongue and the pituitary body are of different embryological derivation. It was deemed best, nevertheless, to make the experiment. This was encouraging in one way, though disappointing to the patient. Sugar promptly appeared in the urine, confirming our theory,—pituitrin was stopped.

Two very suggestive cases should be mentioned here to demonstrate the intimate and vital relation between lime metabolism and sugar metabolism and the relation of each to cancer.

The first case is one of demonstrated uterine cancer operated upon several years ago by Dr. Hastings. This patient some twenty years ago broke her leg. For no known reason union was very slow, over a year being required for even a

fairly good result. In view of our present studies this seems to have been simply a case of very poor calcium metabolism. The patient has always been and is still fond of sweets. That is, this case tends to show that poor lime metabolism and very active sugar metabolism in a person in middle life furnishes a favorable condition for the development of cancer. One will find, as the writer has repeatedly observed, that cancer patients are usually fond of sweets.

The other case is typically one of moderate hyperpituitarism. He is a young man showing every sign of this condition. He has diabetes insipidus, bilateral temporal hemianopsia, a wide sphenoid. Also, an interesting fact, he has five lower incisors; otherwise he would have the characteristic spaced teeth. Finally, he never cared much for sweet things. He never takes sugar in coffee, for example. This man very recently broke his leg, and a very remarkable thing happened. While the very rapid repair was going on, showing extraordinary lime metabolism, the diabetes insipidus disappeared! This is interpreted to mean that while the extraordinary call for lime salts was readily met, the pituitary was so busy with this extra work that it could not also show at the same time the characteristic polyuria of hyperpituitarism. In four weeks the bone repair was perfect (x-ray proof), no pain, patient walking.

As a suggestion in passing, may we not utilize pituitary extract in most fracture cases to hasten recovery and especially in cases of delayed union? May we not do the same in bone grafting? In rickets and other allied conditions of defective bone development? The field is very wide. The more the relation between lime and sugar is studied the more is one impressed with its importance and with the possibility of practical application in very many diseases of faulty metabolism. In the list of such diseases besides cancer and diabetes may very possibly be found such apparently widely different conditions as psoriasis, arterio-sclerosis, rheumatism, decaying teeth, baldness, some cases of nephritis, obesity and a host of other diseases, the management of which is at present largely unscientific, unsatisfactory and empirical.

CASE 1. Mar. 1, 1913. Miss H. Age about 45. For about a year has had a severe menorrhagia. For about 6 months bleeding not only at regular times but irregularly between times. Was examined by Dr. McCauley who said she had a fibroid. Refused operation. For past 3 or 4 months has had also an irregular yellowish red foul smelling discharge. All the time more or less has had pain and swelling (not altogether oedema) of both legs with severe pain in muscles of both legs. Treated for rheumatism.

Then in January, 1913, began to fail rapidly in flesh and strength. Went to Homeopathic Hospital under Dr. McCauley. Grew steadily worse. In February left hospital, discharged doctor and friends sent for me.

I found her semiconscious, very anemic, weak, pulse rapid and weak. A large smooth mass corresponding to enlarged uterus, a thin foul-smelling discharge from vagina, legs swollen and tender.

Diagnosis—Fibroid with superimposed cancer of utterus.

Prognosis—Death very soon.

Treatment. At first stimulants. Then a little food as she regained consciousness. Finally sugar in excess by all possible means, candy, grape-juice, sweets and all she could use on cereal, in coffee, etc.

Result. Steady improvement in every way. In April she walked several miles, came to office and had gained not only strength but 20 lbs. in weight. In May she pronounced herself well. Since then I have only seen her casually on the street.

The fibroid is there but smaller. There is no bleeding or other discharge and very little swelling of legs.

Clinically this is a case of cancer of the uterus which has recovered. Unfortunately, I have no scientific proof of it. No microscopical examination was made because the case seemed hopeless. If it was indeed cancer, and if our present deduction that cancer is due in this case to hypo-secretion of a ductless gland of mesodermic origin (the uterus being mesodermic) then a seeming difficulty arises, for in this case we acted on the hypothesis that we were dealing with hyper-secretion of some sugar regulating ductless gland which also controlled growth. The idea was to give the gland so much work to do attending to the sugar function that it could not also stimulate growth. We had vaguely in mind the suprarenal and the pituitary, but we were working in the dark. Now the only ductless glands of mesodermic origin are the cortical portion of the suprarenal, the coccygeal body probably, Leydig's cells of the testicles and the ovaries. Leydig's cells being ruled out and probably the coccygeal body, there remain only the cortex of the suprarenal, which is not at all understood as yet, and the ovary. We know that suprarenal extract in excess tends to produce hyperglycemia and it is most suggestive that ovariotomy is followed by hypertrophy of the cortical portion (mesoderm) of the suprarenal. Therefore hypo-ovarianism, our present tentative hypothesis as to the ultimate causative agency in producing uterine cancer, might easily produce the characteristic hyperglycemia of cancer by first causing hyperadrenalism. Personally I should be strongly inclined in the next case to give ovarian extract.

How could the administration of sugar then have brought about this possible cure?

Several explanations seem possible. In the first place, remember that all our cases showed remarkable initial improvement with subsequent backsliding (except this first case) on the sugar alone. It is conceivable that in the first case the initial gain was just what was needed to turn the scales between cancer growth and no cancer growth, by enabling the relation between hypo-secretion of the ovary and hyper-secretion of the suprarenal cortex to become normal again. This might have happened by overwhelming the suprarenal with sugar work and

thus soon bringing about its atrophy to a degree parallel to the assumed hypo-secreting ovaries. This, of course, is somewhat speculative.

At any rate, the remarkable initial gain in all the cases on a liberal sugar diet is worth considering briefly. I believe the explanation is somewhat as follows: During the growth period sweets are eagerly sought by almost all children. Violent exertion uses up adrenalin, calls for sugar from stored up glycogen, and the system subsequently craves carbohydrates to replace the used-up glycogen in liver and elsewhere; and calls on the suprarenals for more adrenalin. The muscles call loudest for all this. In this connection recall the well-established endurance and lack of fatigue in recent tests on strict vegetarians.

In cancer we have a riotous growth. Therefore a call for sugar, therefore a hyperglycemia but no diabetes because the extra sugar is pounced upon by the growing cells. Sugar is taken from the other body cells so that they do not get even what they require. Therefore they grow weaker and weaker, our well-known cancer symptom. Now give such an individual enormous amounts of sugar. At first the cancer cells are taken by surprise; they have all they want and more. This excess is greedily used by the sugar-famished body cells and they recuperate to such an extent that they all functionate better; even the hyposecreting ductless gland at fault does better work and the cancer cells actually begin to deteriorate under this influence. But with all this extra food the cancer cells soon begin again to grow and to multiply more than before and the short spurt of improvement is over, unless, as assumed in this first case, the improvement is enough to enable the system to obtain complete mastery over the cancer, a necessarily rare occurrence. But that would explain the rare cases of spontaneous cure.

Therefore at present I would be inclined to give the sugar for a short time in order to take advantage of this first gain, but I would also administer in some way an extract of the hyposecreting ductless gland.

CASE 2. Dr. Hastings' patient. Cancer of stomach—inoperable.

Declined treatment after a short trial.

CASE 3. Dr. Hastings' patient. Male. Cancer of stomach—inoperable.

In first month gained two pounds, had no pain and growth palpably smaller. Then initial gain was lost and the patient followed the usual course and died except that there was a noticeable absence of pain and the growth certainly seemed smaller.

CASE 4. April 12, 1913. Mr. P. Age 73. Cancer of skin over sacrum on site of old bed sore contracted in hospital in Civil War times after severe wounds. Growth has been present over two years, gradually growing. At present the whole ulcerated sore measures about 7½ cm. in greatest diameter. This sore is fringed except at top by cauliflower masses. Size of largest mass 2½ x 3 cm. Microscopical examination by Dr. Casey showed typical epithelioma.

Patient also latterly has had diarrhoea and very imperfect rectal control. The assumption was that he had beginning metastasis in the gut.

I have photographs of this case. Also the slides showing microscopical structure.

Treatment begun as usual with addition of sugar as a dressing locally.

May 16. Largest diameter 7 cm. Largest mass 2 x 3 cm. Whole area looks better and masses in general are certainly smaller. But there appear to be new masses coming in the centre of the ulcerated area and the whole sore seems deeper.

Aug. 20. Largest diameter 7 cm. Largest mass 2 x 2½ cm. But central mass persisting and patient is plainly losing weight and strength. He looks badly. Began with pituitrin internally.

Sept. 29. Entire area of ulcer same size but much healthier looking and healing begun at edges.

All the cancerous tissues have shrunken remarkably and the sore is shallow instead of deep. The masses are discrete instead of crowded together with deep sulci between. The largest mass is ½ x barely 2 cm. and not nearly so thick. The whole appearance is changed. One would say that the cancer is disappearing. And yet the man looks badly as he is thin and weak.

At this time (Oct. 1) he was advised to stop taking sugar internally and to eat fats and proteids largely. He was given also strychnine.

On Oct. 5th strychnine stopped and parathyroid begun with the idea of stopping muscle waste.

Oct. 14th. Stronger, eating better.

Since October 14th this patient with short periods of improvement in general health steadily failed in spite of the remarkable disappearance of the cancer. He ate and slept well and was free from pain. On November 27th he died. His only symptoms during the last two or three months of life were polyuria, loss of weight, and especially progressive asthenia of body and mind. The muscular weakness was most marked in the legs. All of which is suggestive in this case of hypopituitarism. We should perhaps have given very large doses of the gland.

Autopsy by Dr. Casey (friends allowed the head only to be examined). Cavity of Sella very narrow fore and aft (.5cm.). Narrowing caused by great increase in bone forming posterior part of Sella. Pituitary body .5cm. x .75cm. about one half normal size. (Biedl.) Microscopical examination (Dr. Casey). (Zenker's fluid—Eosine and Haematoxylin Stain.)

Pars anterior—Eosinophile cells scanty—nuclei ill defined. Cyanophile cells—none observed. The bulk of the cells seem to be of the chromophobe variety. No colloid.

The posterior portion conforms well enough to the histological descriptions except that connective tissue seems largely to have taken the place of the neuroglia.

Inasmuch as histologists differ as to what is normal and our own experience is very limited in this matter we cannot venture any conclusions from the microscopical examination except that absence of colloid and of all but chromophobe cells together with the small size of the gland seem enough to assure us that there was indeed a hypopituitarism.

CASE 5. Dr. Nugent's case. Woman. Aged about 60. Cancer of the oesophagus, with microscopical proof.

Treatment begun about April 16. This patient also was relieved of pain in swallowing and the growth seemed smaller. But she, too, after this initial improvement grew worse and died in the summer of a metastasis in the lung.

CASE 6. Dr. Roseboom's case. May, 1913. Male, 64. Cancer of tongue. Two years' duration.

Treatment begun as usual and the same prompt initial effects observed. Patient said masses seemed flattened out and he had no more pain. But in August when I saw him the regular retrogression had begun.

For reasons given in the body of this discussion we gave him first adrenalin which promptly produced its characteristic sugar effects; then adrenalin and thyroid. No improvement at all. In fact the pain was returning and he complained of feeling weak. Then he was given parathyroid and advised to stop the sugar. This was Oct. 1st.

Oct. 15. He has gained in weight 1½ lbs. in 1 week and feels stronger.

CASE 7. Dr. Jameson's case. Inoperable cancer of pylorus, gall passages and head of pancreas. Exploratory incision and later gastroenterostomy to relieve the obstruction. Patient's family told there was no hope of saving life. As often after such an operation there was improvement and the patient asked if she might eat candy. Dr. Jameson who knew of my first case, urged her to eat all she liked and other sweets too. Now, some six months later, she seems well and no mass can be felt. Of course the mass may have been largely inflammatory and no microscopical examination was made. But in the opinions of the very competent surgeons who saw the mass at the two different operations, there is no doubt at all.

CASE 8. Cancer of the breast. Dr. Mulligan's case.

Small nodule removed November, 1912, as precaution against possible cancer. Examination proved it to be actually already a cancer. In April recurrence with involvement of axillary glands. An extensive operation was then done and the patient subsequently given large amounts of sugar. There has never been an alimentary glycosuria produced, the patient has gained fifteen pounds, and there is as yet no sign of return.

These last two cases would seem to indicate that our experience in the first case cannot be so rare after all. The time is too short, however, to draw any certain conclusions.

(To be continued.)

HOSPITAL CONCERTS FOR FEBRUARY.—The concerts of the Boston Hospital Music Fund for February have been announced as follows:—

Feb. 1—Boston City Hospital (second visit).
Feb. 8—Home for Aged Colored Women.
Feb. 13—State Asylum, Bridgewater.
Feb. 15—Collis P. Huntington Hospital.
Feb. 22—Children's Hospital.

Medical Progress.

FOURTH REPORT OF PROGRESS IN ORTHOPEDIC SURGERY.

BY ROBERT B. OSGOOD, M.D., F.A.C.S; ROBERT SOUTTER, M.D., F.A.C.S.; HERMANN BUCHOLZ, M.D., HARRY C. LOW, M.D., BOSTON.

(Concluded from page 135.)

CONGENITAL DISLOCATION OF THE HIP.

Hayashi and Matsucka[30], [31] have studied the relation of heredity to congenital dislocation of the hip, reviewing the literature from the time of Paré. Among the authors' 230 cases, 14 they considered hereditary and 4 familiary. They have also noted the association of other congenital deformities with congenital dislocation of the hip. Twenty-five of their 230 cases showed other deformities and they have collected 140 cases showing other congenital defects from an extensive review of the literature. Contractures of the legs in hyperextension and outward rotation of the hips are the most common deformities, and club foot, genu recurvatum, spina bifida, and wry neck follow in the order given.

Galeazzi[32] believes that antetorsion of the upper end of the femur is the chief factor in the deformity of congenital dislocation. The method of reduction which he follows is based on this belief. He first inwardly rotates in proportion to the amount of antetorsion. He next slightly flexes and abducts, applies slight traction, and exerts pressure on the greater trochanter. The method is useless, (1) in cases with marked relaxation of the capsule and ligaments, (2) in cases with rudimentary development of the acetabulum, or (3) in cases when after the rotation the distance between the femur and the acetabulum remains unchanged. His first plaster is applied in inward rotation with slight flexion and abduction. In from 12-15 days a control x-ray is taken and a second cast applied to remain on 60-70 days. At the end of this time a third cast is applied with less abduction and flexion. He reports 30 cases successfully treated by this method.

Lorenz[33] thinks that many cases showing a moderate amount of antetorsion do not need special consideration because the chances of spontaneous correction of the deformity are fair. He admits, however, that in marked antetorsion something must be done to secure good final function. To overcome the difficulty he reduces the hip and stretches it sufficiently so that it slips in and out easily. He then performs a supracondylar osteoclasis and outwardly rotates the lower fragment as much as is necessary. The hip is now finally reduced and plaster applied. In certain cases in which the reduction has proved too difficult to be safe after the os-

teoclasis he corrects the position and three months later, after the fracture is firm, he makes a final forcible reduction.

Ludloff[34] still maintains that in many cases the bloodless reduction does not avail, and in these cases he makes the reduction by open operation. He uses an anterior incision about five inches long, starting from Poupart's ligament and continued down along the outer border of the adductor longus. He believes that this incision offers the best opportunity for clearing out the interposed capsule and deepening and moulding the anterior wall of the acetabulum. He cautions against "boring out" the acetabulum, which leads to ankylosis.

Bibergeil[35] has studied the late sequelae after the reduction of congenital dislocations of the hip. He finds that frequently quite marked changes resembling arthritis deformans and coxa vara and valga occur. In many of these cases the function of the joint is remarkably good, indeed much better than x-ray appearances would suggest. Bibergeil believes the which takes place at the time of reduction, and urges that trauma be avoided wherever possible on account of these late important changes.

CLUB FOOT.

Eikenbary[36] calls attention to the imperfect nature of the term "equino varus" as descriptive of club foot. His point is well made when he says that adduction of the foot at the midtarsal joint is a most important and least often corrected part of the deformity. He leaves the equinus for last correction, and statistically proves the practical safety of tenotomy as far as danger of non-union is concerned.

(Ed. Note.—We admit that non-union is a practically negligible danger under proper technic, but too free and careless section often results in the formation of much scar tissue and a loss of contour and a clear outline of the tendo Achilles. Possible subsequent tenotomies or tendon lengthening are made much more difficult, and we have lately employed in all marked cases either a careful open tendon lengthening with closure of the sheath, or the subcutaneous zigzag method of Bayer, believing these to be better procedures in cases which have extreme degrees of equinus persisting after the varus and the adduction of the fore part of the foot has been corrected.

Hoke[37] in nearly all cases does an osteotomy of the metatarsals at their bases or midtarsal ends. There is no disturbance of growth, and after thorough manipulation of the tarsus, this procedure often obviates the necessity for the removal of large bone wedges from the tarsus. The removal of these wedges may interfere seriously with the future growth of the foot.

RICKETS, OSTEOMALACIA, COXA VARA, ETC.

Discussion as to the etiology of rickets still continues, and while those who hold it to be some disturbance of metabolism connected with nutrition seem to be in the majority, the infection theory is apparently winning strong partisans. Thus Ribbert[38] maintains that disturbances of lime salt metabolism play no rôle in the etiology, despite the clinical experiences of the association of faulty nutrition and metabolic disturbances. Experimentally he believes rickets may be produced by bacterial infection and by excision of the thymus gland. The findings of necroses of the cartilagenous cells in the region of endochondral ossification suggest an infection also.

Kassowitz[39] considers that the increased formation of blood vessels and medullary spaces is also an evidence of some infection, and mentions the fact of its frequent appearance in children of apparent normal digestion and sometimes even in infants well fed by the breast.

Dibbelt,[40] on the other hand, is unwilling to admit the infectious theory of Ribbert and Kassowitz, maintaining that the changes in the secretion and excretion of lime salts which can be observed in the acute stage, can only be explained on the theory of a disturbance in lime salt metabolism.

Osteomalacia. Stocker[41] reviews his experimental research based on the assumption that osteomalacia is the result of excessive or perverted function of the ovaries and testicles. He has implanted into the preperitoneal tissue of rabbits, calves, and dogs, ovaries and testicles of other animals of the same species, thus inducing an extra supply of the internal secretion. In rabbits the results were negative, but he points out that osteomalacia has never been recorded in rabbits. In calves and dogs signs of softening of the bones were seen within five months. There seemed to be no doubt that the implants continued to secrete and that the excess of hormones from the sexual glands influenced the metabolism. The softening resembled in all respects that seen in rickets and osteomalacia. In these diseases we have no means of checking the hypersecretion of these glands except by their removal, but Stocker suggests that these deleterious oversecretions may be checked by supplying a larger amount of the antagonistic hormones to restore the balance between the internal secretions. This has been realized by Bossi[42] with epinephrin in osteomalacia. Bab[43] has reported great success with hypophysis extract, and Stocker himself has obtained notable improvement with thyroid treatment.

At the German Orthopedic Congress Schulz, in discussing the causes of coxa vara of adolescents expressed the belief that it was due to a hypoplasia of the genital glands and a consequent disturbance of the secretion, an opinion concurred in by Foersth.

Albrecht, in discussing a paper of Fritz Wassermann, outlined the known effect of the internal secretions on the growth of bone as follows: Hyperplasia of the hypophysis causes excessive growth. Partial excision of its ante-

rior lobe causes marked disturbance of growth. Castration in early childhood causes persistence of the epiphyseal lines. Excision of the thyroid and of the suprarenals disturbs the longitudinal growth of the bones.

SCOLIOSIS.

Doerr,[44] making exact measurements of 220 cases of scoliosis in Prof. Lange's clinic in Munich, found that in about 7% of the cases there existed a static defect. His statistics are similar to those of Schultbess, who considered that about 5% could be attributed to some static error. Doerr calls attention to the importance of examination of the whole static unit, *i.e.* leg and pelvis, especially in those cases with a lumbar curve.

Nageotte and Wilbouchewitch,[45] as a result of radiographic study, believe that a scoliosis arising from malformation of the fifth lumbar vertebra can be corrected by raising the sole of the appropriate foot. The early recognition of the abnormality is, of course, important. They say that the young and malleable vertebra yields to the action of the weight of the body when the foot is thus raised and that gradually the symmetry of the fifth vertebra is restored, or a compensating malformation in the fourth is developed.

(Ed. Note.—While we do not wish to belittle the importance of static error as a cause of scoliosis, it is surely interesting to note in how small a percentage of scoliosis there is any static error to be detected by exact measurement, as the statistics of Doerr and Schulthess show. It is conversely true that frequently extreme degrees of faulty statics exist for many years without causing any structural change in the vertebral column. Cases of early hip disease and short legs from various lesions, show as a class surprisingly little tendency to the development of a scoliosis. It would seem as if there must be in many of the types some cause other than faulty statics or numerical variation or vertebral abnormality. Nathan[46] offered the suggestion several years ago that we might well suppose some underlying general osseus change of structure which produced a marked predisposition to change of shape when even slight and under other conditions unimportant static defects existed. We are inclined to believe that only on this somewhat vague supposition can many of the complex phenomena of scoliosis be explained.)

Spitzy[47] considers the utilization of the forces of respiration, advocated in America by Hoke and Andrews[48] in 1907, to be a most important factor in the treatment of scoliosis, and reports 14 cases in which he has used the method of Abbott with great success.

Lovett,[49] in a review of the treatment of lateral curvature of the spine read at the Seventeenth International Medical Congress, said that in his opinion the method of Abbott "offered on the whole distinct anatomical advantages and the greatest ease of correction, but the method must be regarded as being to a certain extent still sub judice."

Forbes[50] in Montreal and Adams[51] in Boston report satisfactory results by the use of Forbes' method of rotation in a flexed position.

MUSCLES AND TENDONS.

Coley,[52] in an article entitled "Myositis Ossificans Traumatica," calls attention to the importance of differentiating between this type of bony growth and sarcoma, especially of the periosteal type. From periostitis and osteomyelitis it may usually be distinguished by the absence of fever, local tenderness, and night pain, but with the x-ray alone the difficulty of differentiating a myositis ossificans traumatica from a sarcoma would be great. In Coley's cases the x-rays were repeatedly diagnosed as the more serious condition. The sharp outline dividing the tumor from the bone is an important characteristic, and this is only seen in the earlier cases of sarcoma, and then somewhat indistinctly. The history of definite trauma is almost always to be obtained in the cases of myositis ossificans. The growth is uniformly hard on palpation, while in sarcoma it is softer or has irregular consistency with softer areas. Moderate pain and loss of function are more often noted in this condition than in sarcoma. Microscopic examination should be made whenever possible and at times is the only sure method of differential diagnosis.

Ryan[53] reports 4 cases of what he considers muscle degeneration and osteoma developing either after trauma or as the result of an infection. Three of his cases may possibly represent injuries to the periosteum and subsequent bony proliferation. The fourth suggests the myositis ossificans traumatica such as Coley has described.

Tendon Regeneration. Henderson's[54] experiments with tendon regeneration on five dogs seem to bear out the conclusions of Sever[55] and others, that the sheath is of great importance to perfect tendon regeneration. The experiment in which one and one-half inches of the tendo Achilles was resected, but the sheath preserved, showed as perfect and as quick regeneration as the last three cases in which the same procedure was followed but the defect bridged by two linen threads. In fact, Henderson thought that the threads seemed to retard rather than hasten union.

BONE TUMORS.

Bone Cysts. Canaguier[56] reviews the literature of bone cysts and concludes from a histological point of view that the great difference in the tissue findings in different cases suggests a different origin in many cases. Along with von Haberer, he considers that all simple bone cysts should not be grouped in one single class, and he believes that they originate from one of

three causes: 1. Cysts forming in the centre of a solid bone tumor (most frequently sarcoma). 2. Cysts due to osteitis fibrosa. 3. Cysts resulting from chronic inflammatory processes. 4. Cysts originating as bony hematoma following trauma.

Lejas[57] has encountered five cases of pathologic bone growth in front of the hip joint. They deceptively simulated sarcomas, but examination showed nothing malignant about the growths. They all had a history of trauma from two to four years previously. After a period of insidious development the tumor suddenly increased in size and caused pain in the use of the limb. In all his cases the growth was removed by chisel and mallet and as completely as possible.

Brackett[58] has cut down upon one such case which had been mistaken for tuberculosis of the hip by able orthopedic surgeons. The removal of the growth, in this case small and only suggested in the radiograph, has resulted in the relief of pain and muscle spasm and the return of function.

Kolb[59] believes that all sarcoma-like tumors of the bones, especially those of the skull, should suggest the possibility of metastases of thyroid tissue. He reports the case of a woman of 75 years who had had a goiter removed seven years previously. A tumor of three months duration was removed from the skull and showed the structure of the thyroid gland. Several smaller tumors were found in the lungs. Of 59 cases collected by Regensburger, 25 were in the skull. The tumor grows very slowly, 13 of the patients living 1-2 years; 7 lived 2-4 years; 7 lived from 5-17 years. The thyroid is not always, but is generally enlarged. The spine, next to the skull, and the long bones, next to the spine, are the favorite seats of these tumors.

Ward[60] reports three cases of bone metastases in cancer in which the blood examination showed an increase of the irregular forms of red blood corpuscles, and in a case of cancer of the stomach reported by Harrington and Kennedy[16] in which there were bone metastases in the sternum, rib, and femur, the blood resembled that of a pernicious anemia. They believe that in any case of grave anaemia in which pains in the bones occur the suspicion of metastases should always be aroused.

FRACTURES.

Grässner[62] calls attention to the frequently unrecognized fractures of the centres of ossification. He believes they are by no means as rare as supposed, and reports cases which he has seen occurring in the metatarsus, phalanges, external and internal malleoli, the lower epiphysis of the femur, humerus and radius, as well as the head of the humerus. The cause has always been direct trauma. The importance of diagnosis by means of the Roentgen ray and the abstinence from weight bearing is evident. The end results when proper precautions are taken are excellent.

Wallace[63], in describing fracture of the wrist due to automobile cranking, points out that besides the typical chauffeur's fracture of a direct transverse break of the lower end of the radius, one meets fractures of the scaphoid generally through the middle or inner half and frequently associated with this a dislocation of the semilunar. He states that these injuries may be brought about in one of three ways: 1, by direct violence; 2. by violence plus abduction; 3. by compression between the crank and the radius. Most of the carpal injuries may be replaced but failing of this, the fragment of the scaphoid of the displaced semilunar should be removed.

Turner Thomas[64] has applied a new method of treatment to old unreduced dislocations of the shoulder. This method is a modification of the method of Allis, and consists of traction on the humerus at right angles to the body, fixation of the scapula, and downward pull on the head of the bone. He places one foot on the scapula and the top of the shoulder and the other on the side of the thorax below the axilla. The surgeon pulls upon the adducted arm flexed at the elbow while an assistant pulls downward on the head, manipulating it into place. The advantages of his method over others are (1) that the danger of injury to the vessels and nerves of the axilla by the heel is avoided; (2) the head is brought back into place by a reversion of the course it has followed in the dislocation; (3) there is less danger of fracture of the humerus than in the reduction by external rotation. By this abduction method the force driving the head into the socket is directly applied and there is no long leverage. The Bigelow and the Kocher methods are not available in cases complicated by fracture, while in these cases this traction abduction method may safely be adopted. Thomas, after a study of the cadaver, is firmly convinced that the head cannot escape from the socket through the linear tear of the capsule that Kocher describes. A further tear at right angles he believes necessary. The torn capsule is closely bound about the neck and the chief obstacle to reduction is the cicatricial tissue formed along the torn edges of the capsule and the contractions of the capsule, especially of the posterior portion. He agrees with Lund[65] that after six weeks, changes have taken place that render manipulative reduction improbable.

Gibson[66], reporting a successful open reduction by a posterior incision of an old dislocated hip in a patient 49 years old, is convinced that here too, the likelihood of safe reduction in adults after eight weeks is little. In his case neither reduction under ether nor traction in bed with weight and pulley were successful, and at operation the acetabulum was found obliterated by the torn capsule.

An unusual dislocation of the left os innominatum has been reported by Fiaschi[67]. A ten year old boy was struck on the crest of the left ilium a glancing blow by a falling iron fence. There was a protrusion over the left

sacro iliac joint. The x-ray showed the whole left side of the pelvis higher than the right, the pubic bone being elevated on that side one inch. There had been apparently a nearly complete dislocation of the left os innominatum by the blow and later an upward displacement owing to the pull of the adbominal and back muscles. Under ether this displacement was at least partially reduced and a fairly good functional recovery was made.

(Ed. Note. We have observed one case and seen Roentgen plates of two others in which a complete or partial dislocation of the ilium at the sacro iliac joint had taken place, the displacement being upward as in this case. In these cases direct violence was the cause and there were complicating pelvic fractures as well.)

Schultze[68] believes that in fractures of the patella it is most important to reconstruct the apparatus of extension. He is extremely careful by means of three double hooks to obtain by suture a most complete coaptation of the edges of the torn capsule. He gets his patients out of bed in 12 days and begins light medico mechanical treatment. Sutures of the bony fragments are usually rendered unnecessary when the capsule is accurately repaired and sutures of the bone fragments alone he considers insufficient for the return of perfect function.

Foraze and Salle[69] have studied fractures of the astragalus and analyzed the commonest forms of break. They advise fixation in plaster for a month and freedom from weight bearing for two months. Where displacement is slight, prognosis is good, but they call attention to the frequency with which obstinate arthritic conditions persist after union is firm. To overcome these common and incapacitating symptoms Stockum[70] has been performing an arthrodesis of the calcaneo astragaloid joint in old painful fractures of the astragalus or os calcis. It is at this joint that most of the painful motion occurs and destroying all this motion has been successful in his hands in relieving symptoms.

MISCELLANEOUS.

Isamoylenko[71] has made a histological investigation of the function of the endosteum in 22 human cases, varying in age from embryonic life to over 80 years. He concludes that the endosteum is a connective tissue, having the same functions as the periosteum, namely bone formation and bone absorption. The endosteum is entirely different from the bone marrow, forming a connective tissue framework for this structure. The marrow does not share in bone regeneration and cannot exist independently from the endosteum. On the other hand, the endosteum can live without any connection with the marrow.

Smith[72] has studied skiagraphs of the hands and forearms of 914 naval students in order to determine whether the degree of development of the fourteen epiphyses which these plates show will give any index in these sub adult cases of normality or precociousness or delayed development of the individuals. He concludes that while in children this method of Roteh[73] may be of value, it is in the cases studied unsatisfactory.

Pieri[74] has had successful results in spina bifida by transplanting grafts of fascia from the thigh to close the opening in the canal. The graft is placed between the subcutaneous cellular tissue and the cavity of the spine, and the skin is brought over this.

Reports of Societies.

TRANSACTIONS OF THE AMERICAN SOCIETY FOR THE PROMOTION OF CLINICAL RESEARCH, WASHINGTON, D. C.

MAY 5, 1913.

MORNING SESSION. CALLED TO ORDER BY THE PRESIDENT, DR. W. S. THAYER, AT 10.00 A.M.

DR. THAYER said: The functions of this organization are set forth completely in the title. The idea underlying the formation of the Society was to gather together medical men, and particularly young men, in order to stimulate and encourage by our mutual efforts the undertaking and putting forth of original research work. It is thus a society of clinicians who desire to do more than merely practice medicine.

With these objects of the Society in view, the council has acted in making recommendations for election to membership.

We will proceed with the scientific program; but before calling for the papers, I beg leave to exhibit an unusual polygraphic tracing for your discussion, and to make a clinical observation.

The tracing is from a patient, whose history is as follows: For six months he has had attacks of the Adams-Stokes' syndrome. When seen by me he had been in bed for two weeks recovering from a very severe paroxysm, during which the pulse had been as low as 30. When I saw him the pulse was 36, the heart somewhat enlarged, the sounds clear; but between the beats I thought I could hear an additional slight sound.

Analysis of the tracing shows that between each ventricular beat, there is a characteristic auricular impulse, which explained the sound heard between heart beats.

It will be noticed that the C wave has a notch on the katacrotic limb, which evidently is another auricular wave; it would seem, therefore, that in this case we are dealing with 2: 1 rhythm heart block, with a very unusually long interval between the auricular and the ventricular contractions.

The clinical observation I wish to make is in connection with the case of a man seen about two years ago. This man had had polyarthritis, followed by dyspnea on exertion and cyanosis. He had been ill about two months when I saw him; he was cyanotic and the veins of the neck were much distended. It was evident that there was some obstruction of the superior vena cava. Physical examination showed that there was present a large pericardial effusion.

Upon lying down the whole picture changed; the cyanosis disappeared and the distended veins subsided. In the course of a few months, the pericardial effusion cleared up and the symptoms were all much better. Later the patient died, but no autopsy was obtained.

This man had been on his feet and had been going about with an old pericardial effusion. It seems possible that the heavy pericardial sack, in the erect posture, by tugging at the base of the heart may have caused a certain amount of stenosis of the superior cava. There is no other such case recorded in the literature so far as I have searched.

Is orthopnea a symptom of pericardial effusion? I have been struck by its absence, although the dyspnea may be great. In pleural effusions orthopnea is the rule. May not the explanation just advanced correctly explain this difference?

ETIOLOGY OF ACUTE MUSCULAR AND ARTICULAR RHEUMATISM.

DR. E. C. ROSENOW, Chicago.

By planting the joint fluid and other material in acites-dextrose agar it has been possible to isolate organisms of the type described by Poynton and Payne from twelve out of fourteen cases of typical acute articular rheumatism. The organisms are never numerous in the free joint cavity but are present in larger numbers in the lesions of the para-articular structures. In order to obtain positive results it is quite necessary to make the cultures within forty-eight hours of onset of the pain in a given joint or soon after exacerbation. This is true to even a greater degree in case of blood cultures. In two out of four cases the organism was isolated from the blood at the height of the attack.

Culturally and morphologically the organisms resemble more closely streptococcus viridans than hemolytic streptococcus. Nearly all strains fermented mannite and when first isolated produced a very high degree of acidity in dextrose broth and grew better at low temperature than the other members of the streptococcus group.

Their virulence to warm-blooded animals is greater than streptococcus viridans but less than the common hemolytic streptococcus and of course pneumococcus. The virulence to cold-blooded animals on the other hand (frogs at 22° C.) is greater than hemolytic streptococci and highly virulent pneumococci. But when frogs are placed at 37° C. the relative virulence of these strains is again the same as to warm-blooded animals. These facts may explain why exposure to cold aggravates so strikingly the symptoms in rheumatism. While the cultural and other features of these organisms resemble closely streptococcus viridans and hemolytic streptococcus they behave quite differently when injected intravenously in animals. Multiple non-suppurative arthritis and endocarditis of the rheumatic type, pericarditis and myocarditis have been produced repeatedly in the same animal. The lesions about the joints occur in relatively avascular regions. The number of organisms here just as in the human is greater than in the joint cavity. The endocarditis due to these organisms, just as I have shown to be the case in streptococcus viridans endocarditis, has been proven to be embolic in origin. But the vegetations remain small and often do not break through the endocardium. This is in marked contrast to the type of lesion produced by streptococcus viridans where the vegetations become large and ulcerated. This difference is shown beautifully by the specimens.

By modifications of these organisms and by two strains obtained from cases in which muscular involvement was present it has been possible to produce in rabbits, dogs and in one monkey extensive non-suppurative myositis. The distribution of these lesions is quite like that in human muscular rheumatism. The lesions are most numerous in the flat

muscles about the neck, shoulders and spine, the intercostal and belly muscles; less often the diaphragm and the more tendinous portions of the muscles of the extremities. When the affinity for the skeletal muscles is great the myocardium shows especially marked degeneration and there is now usually also nephritis but the affinity for endocardium and joints is distinctly less than before.

DISCUSSION.

DR. R. I. COLE, New York: Is there any specific biological test for infection with this organism?

DR. R. PEMBERTON, Philadelphia: Has Dr. Rosenow extended his observations so as to study chronic effusions in joints? I have in mind cases of the rheumatoid arthritis group.

DR. W. T. LONGCOPE, New York: What happens when the virulence of this particular strain of cocci is increased? Do you ever then find that the more acute vegetative changes occur in the heart?

DR. E. C. ROSENOW, Chicago: I have found no special biologic test for this organism. The property of producing the typical rheumatic lesions is present for only a short time after cultivation of micrococcus rheumaticus. To test this out, a culture was taken from the tonsil early in an attack of acute rheumatism: the organism was identical with the organism obtained from rheumatic joints, and produced the same lesions on inoculation. Later cultures, taken after the lapse of four days and eight days respectively, no longer produced joint lesions, but did cause endocarditis. After a month in a hypotonic solution (distilled water), the organism grew differently and produced in animals myositis and myocarditis. Whenever the tendency is to invade muscles, the organism also tends to cause myocardial degeneration.

As to the chronic lesions of joints, as in rheumatoid arthritis, I feel sure that this organism is not to be found in such joints; one is more apt to find the streptococcus viridans.

When the virulence of the micrococcus is enhanced, joints are no longer involved, but endocardial change is the rule.

I have been able to convert the micrococcus rheumaticus into streptococcus pyogenes, into pneumococcus, and into other strains.

A CONSIDERATION OF SOME OF THE PROBLEMS RELATING TO THE ORIGIN AND TRANSMISSION OF THE INFECTION IN EPIDEMIC STREPTOCOCCUS SORE THROAT.

DR. J. A. CAPPS, Chicago.

In some epidemics of septic sore throat the infection can be easily traced to one milk supply; in others the clinical data require painstaking study. An epidemic in Batavia was graphically described to illustrate how several dairies can share in the spread of infection by means of interchanging bottles with the primary offender.

Another small epidemic was unearthed in Oak Park by tracing the milk from a herd of diseased cows to the consumers. Small outbreaks due to milk are probably very common in the smaller cities and should be recognized.

The evidence obtained on the farms points strongly to streptococcus mastitis as the principal source of contamination.

EXPERIMENTAL BOVINE MASTITIS PRODUCED BY HUMAN THROAT STREPTOCOCCI.

DR. DAVID J. DAVIS, Chicago.

The source of the Chicago milk epidemic of 1911-12 was traced by Capps and Miller (*Journal American Medical Association*, 1912, v. 58, p. 1848) to certain farms in the region of Batavia, Ill., where the milk supply of the suspicious dairy was obtained. On a number of farms sore throat in the milkers and mastitis in the cows were associated. In some instances the mastitis preceded the sore throats in the milkers and in other instances the sore throat preceded the mastitis in the cows. It was necessary, therefore, to consider the possibility that the mastitis was caused through the infection of the teats and udders of the cows by the milkers. This consideration also involved the question of the susceptibility of the cow to human streptococci. In attempting to throw some light on these problems the following experiments were made.

From the tonsils of a patient suffering with a typical and moderately severe acute tonsillitis an ordinary hemolytic streptococcus was obtained in pure culture. This organism was first smeared on the surface and over the ends of the teats of a healthy cow. Also some of the exudate direct from the throat was applied in a similar manner. The results were negative. Two other strains of human streptococci were applied in the same way without result.

Next a slight abrasion of the skin was made near the meatus at the end of one of the teats and the throat streptococcus was applied as before. Local infection resulted in twenty-four hours. After several days the infection extended into the udder as manifested by the presence of streptococci and other germs and an increase of pus cells in the milk from this quarter. There was no caking of the udder and little or no swelling of the quarter. The streptococci continued to be discharged in the milk for over two weeks.

Into another quarter a culture of the throat streptococcus in milk was injected through a small catheter inserted about 8 cm. into the udder. On the following day the milk was stringy and contained enormous numbers of pus cells and streptococci in pure culture. No caking of the udder resulted but moderate swelling with some tenderness was present for a few days. The inflammation gradually subsided but streptococci continued to be discharged in the milk for about four weeks.

During this time no alteration of the properties or the pathogenicity of the streptococcus was noted.

Feeding young rabbits and a monkey with the infected milk caused no symptoms in the animals.

The following conclusions may be drawn:

1. Hemolytic streptococci from the human throat may cause mastitis in cows.

2. The streptococci and the increase in pus cells may persist in the milk for several weeks, a point which may be brought into relation with the duration of milk epidemics of septic sore throat.

3. An abrasion of the teat may be the atrium of infection. It would appear to be possible, therefore, for mastitis in cows to be produced by an infection from the milker whose hands were contaminated, perhaps, from a sore throat.

4. Caked udder or ropy milk may or may not be present. Hence, an ordinary physical examina-

tion of a cow might not be sufficient to detect a streptococcus mastitis. Bacteriological examination of the milk carefully obtained from each cow or better from each quarter of the udder might be necessary to detect the source of infection.

DISCUSSION.

DR. JOS. L. MILLER, Chicago: Have any of the members seen epidemics of this sore throat during the past winter? I have seen two cases in people who had recently come from Florida.

DR. HENRY A. CHRISTIAN, Boston: May we infer from these investigations that we are safer if we get our milk in cans along with the other bacteria?

DR. W. S. THAYER, Baltimore: In Baltimore last winter a brief epidemic occurred during a time when the pasteurizing plant was temporarily out of order. The brevity of the epidemic may be understood when I say that I went out of the city for two-weeks' stay; there was then an epidemic, and when I returned the epidemic was over.

Discussion closed.

DR. J. A. CAPPS, Chicago: With regard to the multiplication of bacteria, Theobald Smith says that improper pasteurization may act only as incubation, and thus it may be more a menace than a protection. Dr. Christian's question, I would not attempt an answer; the only inference I would draw would be that the consumers served by the dairy with bad milk profited by the fact that they happened to have a bottle service. It is only safe to conclude that the distribution of milk in bottles, pasteurized in the bottles by the holding process, is the best method of protection thus far devised.

DR. D. J. DAVIS, Chicago: I do not think the inference embodied in Dr. Christian's question necessarily follows from the results of our investigations. It is a fact, however, that streptococci in milk do not multiply as rapidly as do other bacteria, and that they will in the presence of saprophytic organisms eventually disappear.

ABSTRACT.

THE METABOLISM AFTER MEAT-FEEDING OF DOGS IN WHICH PANCREATIC EXTERNAL SECRETION WAS ABSENT.

DR. FRANCIS F. BENEDICT AND DR. JOSEPH H. PRATT, Boston.

Ingestion of various kinds of foodstuffs produces an increase in the total metabolism of both animal and man. Zuntz assumes that this increase is mainly due to the mechanical work of digestion. Rubner, on the other hand, holds that it results from the specific dynamic action of the absorbed foodstuffs. The present study deals with the metabolic changes following the ingestion of meat upon three dogs without external pancreatic secretion in which the absorption of nitrogen and fat was greatly diminished. In these animals the work of the intestines following the ingestion of food was greater than normal, hence, if Zuntz's theory was correct greater increase in the metabolism than that present in a normal dog would be expected. As the absorption of nitrogenous material from the intestine was greatly decreased, there should be according to Rubner's view, less increase of metabolism than seen in the healthy animal.

The carbon dioxide produced was determined by means of a modified form of the Benedict and Homans' respiration apparatus. Kymographic records of muscular activity were kept and all experiments were rejected except those in which the animal was very quiet. Control experiments were made with a normal dog. All four animals were of nearly the same size and weight.

The increment in the carbon dioxide production was found to be larger in the normal dog than in the three dogs with pancreatic achylia. This was particularly true when 750 grams of meat were fed, but also apparent when only 500 grams of meat were given.

The results of these experiments show that there is no large energy transformation incidental to segmentation, peristalsis, glandular activity, and the movement of the unabsorbed food through the intestinal tract. The attempt to explain the increased metabolism following the ingestion of food by the theory that the increase is a consequence of such movements is, therefore, not justifiable.

DISCUSSION.

DR. FRITZ B. TALBOT, Boston: There is one important source of error in such work. Benedict and I in estimating the metabolism of normal babies found that the results depend to a great degree on the amount of muscular activity of the individuals under investigation, and we met with great difficulty in attempting to compare this factor.

DR. S. J. MELTZER, New York: May not another source of error arise from the fact that when the pancreatic external secretion is eliminated some of the glandular activity is also eliminated? Some of these glands need to be activated by the influence of the pancreatic juice.

Discussion closed.

DR. J. H. PRATT, Boston: I recognize the importance of Dr. Talbot's remarks. Benedict first called attention to the necessity of controlling muscular activity, and no practical suggestion has been of greater value than this in conducting the experiments at the Carnegie Institute.

I cannot answer the question proposed by Dr. Meltzer, because the same important and unsolved problem is involved as is encountered in all such work. The same criticism has been made before by Dr. Meltzer, especially in the case of one of my experimental dogs with imperfect gastric function; but in the experiments here reported the stomach secretions seemed normal so far as my examinations could determine.

(*To be continued.*)

Book Reviews.

Annual Registration Report of Michigan. By FREDERICK C. MARTINDALE. Lansing: State Printers. 1913.

This belated forty-fifth annual report of the secretary of state on the registration of births and deaths, marriages and divorces in Michigan for the year 1911, presents the vital statistics of the state for that year. The greater part of the volume consists of the primary tables in which these data are compiled; the remainder of secondary tables and text, in which they are analyzed. The volume is of value to statisticians and students of public health.

THE BOSTON
Medical and Surgical Journal

THURSDAY, JANUARY 29, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

REPORT OF THE COMMITTEE OF THE SOCIETY OF MEDICAL JURISPRUDENCE ON THE LAW OF INSANITY.

IN January, 1912, a committee composed of prominent physicians and members of the bar was appointed in the New York Society of Medical Jurisprudence to consider the desirability of changing the legal measure of responsibility of those mentally diseased or defective, so as to accord more thoroughly with the views of students of the causes of mental defects; and the New York State Bar Association, at its annual meeting in the same month, enlarged the powers of its committee on the treatment of the criminal insane in order to coöperate with this and other similar committees for the purpose named. The committee conferred with Prof. E. R. Keedy of the Northwestern University, Chicago, chairman of Committee B of the American Institute of Criminology and Criminal Law, and learned that his committee had pursued to a very considerable extent the same inquiry it was commissioned to make, limited, however, to criminal responsibility. This Committee B had made, in November, 1911, a preliminary report which contains a valuable bibliography on criminal responsibility of the insane, expert testimony, and miscellaneous matters connected with mental responsibility. The committee then announced its intention to make a thorough investigation into the subject from the standpoint of criminal law; it also suggested, for discussion, a proposed statute changing the present measure of responsibility for crime of those who are mentally deficient.

At a recent meeting of the society the committee, the medical members of which were the president of the society, Dr. Wilcox and Dr. F. W. Robertson, presented its report. This states that there is apparently a well-defined opposition in the entire medical profession to the present legal definition of that kind and degree of insanity which should be a defense for crime. This definition, which was first formulated in England in the McNaghten case, in 1843, and is now crystallized in the New York penal law, declares that: "An act done by a person who is an idiot, imbecile, lunatic or insane is not a crime. A person cannot be tried, sentenced to any punishment, or punished for a crime while he is in a state of idiocy, imbecility, lunacy or insanity, so as to be incapable of understanding the proceeding or making his defense. A person is not excused from criminal liability as an idiot, imbecile, lunatic, or insane person, except upon proof that, at the time of committing the alleged criminal act, he was laboring under such a defect of reason as (1) not to know the nature and quality of the act he was doing, or (2) not to know that the act was wrong." Not only is this definition disapproved as wholly unsatisfactory by most of those professionally engaged in the study and treatment of the insane, but it has now been disproved and rejected as an inadequate definition in some of the courts of this country, while even in England, where the definition was invented by a body of judges presumably unacquainted with the nature of mental disorders, there is a tendency to disregard it in the trial courts. The committee is of the opinion that this definition should be discarded, and that no legal definition is necessary in the present state of our knowledge of mental disorders. The present legal standard holds persons responsible who, in the opinion of the committee, are not capable of avoiding the act committed by them, although they may appreciate its moral and legal qualities. The acts of an individual are largely the results of his mental reactions, and these may be abnormal to such an extent as to make him morally irresponsible for his conduct, in instances where his irresponsibility in fact would be no defense for his acts under the present law. The guide of responsibility, it believes, should be the judgment of the jury, as instructed by the medical witnesses in the case. It is not likely that a jury would convict a person who could

escape under the present legal definition, while a jury might properly acquit, on the ground of insanity, a person whom they should regard as irresponsible for his acts, though not measuring up to the legal definition. The committee, therefore, recommends that the latter portion of Section 1120 of the New York Penal Law should be repealed. This would leave the provisions of the law in respect to mental incapacity as follows:—

"An act done by a person who is an idiot, imbecile, lunatic or insane is not a crime. A person cannot be tried, sentenced to any punishment, or punished for a crime while he is in a state of idiocy, imbecility, lunacy or insanity, so as to be incapable of understanding the proceeding or making his defense"; leaving the jury, under the instructions of the judge and from the evidence in the particular case, to be the judge of what constitutes an idiot, imbecile, lunatic or insane person.

A dissenting minority report was presented by one of the three legal members of the committee, who objected to the repeal recommended, on the ground that it would result in more uncertainty than ever in the prosecution or defense of such alleged criminals, and contended that if the repeal were to be made, some other legal or medical definition ought to be suggested as a guide for jurors and courts in their decisions; for otherwise jurors would be led to speculate too much, and would allow many to go free who are now held accountable. The sentiment expressed at the meeting was entirely in favor of the majority report, which was adopted. In accordance with one of its recommendations, a new committee was instituted to take such steps as may be considered proper to give publicity to the recommendations of the society and secure the ultimate amendment of the penal law accordingly, and the whole matter is to be made the special order of the March meeting of the society.

THE STATUS OF RADIUM AND RADIO-THERAPY.

THE subjects of radium and radiotherapy are at present occupying positions of considerable prominence in both scientific and popular medical literature. The physical properties of radium are so remarkable and almost mysterious as to attract widespread interest and curiosity; and the claims made for the possible therapeutic values of radio-active substances are so striking as to demand careful investigation. Unfortunately, like all new modes of treatment, radiotherapy has already been sensationally over-exploited. It is desirable to assess the claims of its merits and determine, if possible, its actual present status in the field of medicine.

In another column of this issue of the JOURNAL we begin the publication of a continued article by Dr. Delano, of this city, aiming to review the history and literature of radium and to state impartially the case for its value as a therapeutic agent.

From its very nature, the subject of radiotherapy lends itself easily to quackery and charlatanism, and the public needs warning against unreliable users of radium and against undue expectations of its efficacy.

THE executive committee of the American Society for the Control of Cancer has recently prepared for general distribution the following circular, aiming thereby wisely to warn the public against exaggerated claims for the value of the radium treatment of malignant disease, and to prevent the consequent disappointment and suffering in the event of its proving even less salutary than may reasonably be hoped.

"The American Society for the Control of Cancer fears that exaggerated ideas of the power of radium in the treatment of cancer may result from the recent publicity given to this agent in the daily press. It appears highly important at the present time that the limitations of radium in the control of cancer should be emphasized as well as its favorable effects in certain cases. Otherwise the familiar story of new hopes, destined only to disappointment, will again be recorded at the expense of many unfortunate sufferers.

"The curative effects of radium are practically limited today to superficial cancers of the skin, to superficial growths of mucous membrane which are not true cancers, and to some deeper lying tumors of bone, etc., which are not very malignant. The problem of the constitutional treatment of advanced, inoperable cancer is still untouched by any method yet devised or likely to be devised for administering radium. Even among the so-called radium cures, it still remains to be determined in many cases whether the favorable result is permanent or is to be followed sooner or later by the usual recurrence. The most competent surgeons do not dare to pronounce a case cured until five years have elapsed after an apparently succesful operation. The same test must be applied before we can finally determine the real value of radium.

"It should be emphasized especially that radium cannot at present exert any permanent benefit on generalized cancer, and since cancer,

in a very large proportion of cases, is widely disseminated in the body early in the course of the disease, this entire group of cases can expect no important relief from radium. Another large group of cancers is comparatively inaccessible to the application of radium, so that the ultimate course of the disease is not affected, although certain portions of the tumor may be reduced in size. Again, many forms of cancer, although localized and accessible to radium, grow very rapidly and resist the curative action of this agent, so that no real benefit can be expected from its use.

"The best results of radium therapy can be secured only when comparatively large amounts are available for use and the present limited world's supply of this metal places it out of reach of the great majority of patients. It is to be feared that much harm may result from undue reliance upon small quantities of low grade radium when other methods of treatment would be more effective.

"Evidence of the possible extent of popular misconception on this subject is found in a pathetic letter recently received at the New York Health Department from a sufferer in California, who had somehow obtained the impression that the United States Government was about to purchase large quantities of radium from abroad. Assuming that the 'New York City physician' would have a plentiful supply, the writer asked that some be sent to him C. O. D. without delaying to advise him as to the cost.

"Under the term 'cancer' are commonly grouped several diseases which differ widely in nature, causation, and courses, and in their response to radium. It requires both skill and experience to determine just what type of cancer one has to deal with as well as the advisability of using radium. Hence, it is extremely difficult to formulate an accurate statement of the true position of radium therapy, but it is quite clear that the exploitation of this remedy as a cure of cancer in general is to be deprecated."

Considerable attention has also been attracted by alleged commercial attempts to control the supply of radium, in order to maintain or even raise its already almost prohibitive price. To prevent such an occurrence in this country, a proposal has been made by Mr. Lane, United States secretary of the interior, to withdraw from entry all lands of the public domain suspected of containing deposits of carnotite or other radium-bearing ore, in order that these may be secured for the common good and not become the object of private speculation. A bill to this effect has been introduced into the national legislation by Mr. Foster, chairman of the House committee on mines and mining. At hearings held in Washington on this subject, numerous physicians have appeared in behalf of the bill. Such a measure of conservation seems certainly wise, at least until such time as the actual therapeutic value of radium shall have been more accurately appraised.

CONSTITUTIONALITY OF EUGENICS.

THE operation of the so-called "eugenic law" in Wisconsin has already involved legal complications. On Jan. 2 an applicant for a marriage license was refused because he did not have a certificate of examination. He immediately carried the matter before the local circuit court as a test case; and, on Jan. 20, Judge Eschweiler handed down a decision declaring the law unconstitutional.

"The law is praised because of its movement toward suppression of venereal diseases, but is condemned because its enforcement is practically an impossibility.

"The court held that, if the state wishes to exercise its right for preventing undesirables from marriage, it should assume the burden of weeding out the unfit, and thereby not cast upon the fit an unfair demand and thus materially impair an inalienable right.

"The prayer of the plaintiff that the law was class legislation by demanding tests from men only, is refused. The judge said that this was a legislative right. He also overruled the objection to the clause in the law which provides that all examining physicians must be 30 years old or older, because that feature of the law does not affect the rights of the petitioner."

The case has been appealed to the supreme court. Meantime the plaintiff has been granted a license without examination.

MEDICAL NOTES.

A PROLIFIC MOTHER.—Report from Briesen, West Prussia, states that Mrs. Schmidt of that city, has recently given birth to her thirtieth child. She has had several multiple pregnancies.

FOUR LIVING SURREY CENTENARIANS.—Report from London states that there are at present four living centenarians in Surrey,—three being one hundred years old, and the fourth, Mr. John Durant, of Weybridge, having been born on Feb. 2, 1810.

RATES OF EUROPEAN POPULATION INCREASE.—Statistics recently published in London show the relative rates of increase in population of the various countries of Europe in 1911. The six nations having the most rapid growth are Bulgaria, Roumania, Russia, Portugal, Servia and Bosnia. Germany stands eleventh, with an increase of 113 per 10,000 of population. In Scotland the rate was 105, in England 98, Austria 95, Belgium 85, Switzerland 84, Spain 81, Ireland 67, and France 9. The rate of increase in Bulgaria was 188.

BOSTON AND NEW ENGLAND.

TYPHOID FEVER IN BOSTON.—There is at present an epidemic of 55 cases of typhoid fever in Roxbury and Jamaica Plain. The outbreak has been traced to a milk supply infected by a carrier. This supply has now been excluded from the market, and germal antityphoid inoculation is advised for local residents.

HOSPITAL BEQUEST.—The will of the late Mary C. Eastman, of Concord, N. H., which was filed in that city on Jan. 15, contains a bequest of $10,000 to the local Margaret Pillsbury Hospital.

SHARON SANATORIUM ELECTION.—At the annual meeting of the corporation and directors of the Sharon Sanatorium, held recently in Boston, Dr. Vincent Y. Bowditch was reelected medical director, and Dr. Walter A. Griffin superintendent.

PRESCRIPTIONS BY THE BOSTON DISPENSARY.—During the year 1913 the pharmacy of the Boston Dispensary filled 76,584 prescriptions, of which 70,556 were for patients coming to the clinics, and 6028 for patients treated in their homes.

SOME BOSTON DEATH-RATES.—During the first ten months of 1913 the total death-rate of Boston was only 16.1 per 1000 inhabitants, and the death-rate of infants under one year was 112 per 1000 births. In the corresponding period, the tuberculosis death-rate was 14.27 per 10,000 inhabitants. In 1876 this rate was 36.65; in 1881, 42.39; in 1890, 33.27; in 1901, 23.67; in 1907, 18.11; and in 1912, 15.18. In 1912 the tuberculosis death-rate of London was 13.5; Chicago, 14.1; Philadelphia, 16.6; New York, 17.0; Baltimore, 23.6; Vienna, 23.7; St. Petersburg, 28.7; Paris, 33.2; and Moscow, 34.4.

SOCIETY OF EXAMINING PHYSICIANS.—At the annual meeting of the Massachusetts Society of Examining Physicians held recently in Boston, papers were read by Dr. William Duane, Dr. Francis H. Williams, Dr. Frederick J. Cotton, of Boston, and Dr. F. W. Anthony, of Haverhill, Mass. Dr. H. H. Hartung was elected president for the ensuing year, Dr. J. H. Stevens secretary, and Dr. John Phelps treasurer.

THE CHILDREN'S HOSPITAL ALUMNI CLUB.—The twelfth annual meeting of the Children's Hospital Alumni was held Thursday, Jan. 8, 1914.

After a "good-bye" visit to the old hospital on Huntington Avenue the alumni were shown the new hospital on Longwood Avenue, by Dr. Robert W. Lovett, following which all repaired to the Harvard Club, where the annual dinner was held at 7 p. m., Dr. Arthur R. Crandell, the retiring president, acting as toast master.

The guests of the club were Dr. E. H. Bradford, Dr. Aurel A. Cook of Hartford, Rev. J. H. Metcalf of Cambridge, and Dr. F. H. Shattuck. Dr. T. M. Rotch, who was to have been a guest, was absent on account of sickness. Besides speeches by the guests, a number of the alumni and the alumni chorus were heard from.

The officers elected for the ensuing year were: Dr. Walter C. Home, president; Dr. D. Crosby Greene, vice-president; Dr. Benjamin E. Wood, member of executive committee; Dr. Arthur T. Legg, secretary and treasurer.

SOCIAL SERVICE AMONG INSANE PATIENTS.—Among the recommendations in the recent report of the Massachusetts State Board of Insanity is one for the appointment of social service workers to follow up discharged cases.

"Needy families, the man or woman of which has been sent to a state hospital, will by this social worker be connected with the proper local agencies. Recommitments may be avoided by assisting in tiding a patient over a critical period.

"Patients who have left the hospital will be heard from more often and the results of hospital treatment more accurately determined. Patients, when they know that a real interest is taken in them, will return to the hospital more often if in need of advice and realizing the return of their mental illness will return for treatment.

"The study of eugenics, although associated with social service, requires workers of special training, and while in certain institutions social work and eugenics may be combined, this board

is of the opinion that they are better done by separate workers."

PETITION BY MILK AND BABY HYGIENE ASSOCIATION.—The Boston Milk and Baby Hygiene Association, in conjunction with the Massachusetts Commission for the Blind, has petitioned the General Court for an appropriation of $1000 for the printing and distribution of pamphlets in English and eight other languages to poor mothers for the purpose of instructing them in the care of their children.

WORK OF BOSTON DISTRICT NURSES.—During the year 1913 the nurses of the Boston Instructive District Nursing Association made 117,228 visits on 11,154 patients, of whom 3954 were mothers with young babies.

MASSACHUSETTS GENERAL HOSPITAL TRAINING SCHOOL.—The annual graduating exercises of the Massachusetts General Hospital Training School were held on Jan. 15 in the new Home for Nurses, which was officially opened on this occasion. Diplomas were awarded to a class of 56 pupil candidates. The principal address, made by Dr. Henry M. Hurd, secretary of The Johns Hopkins Hospital, will be published in a future issue of the JOURNAL.

NEW ENGLAND BAPTIST HOSPITAL TRAINING SCHOOL.—The annual graduating exercises of the New England Baptist Hospital Training School for Nurses were held in Boston on Jan. 27. Diplomas were awarded to a class of eight pupil candidates. The principal address was by Dr. Hugh Cabot on "The Professional Nurse in Relation to Social Problems."

WORK OF CHICKERING HOUSE.—The recently published annual report of Chickering House, Dedham, Mass., records the work of that institution for the year ended Oct. 1, 1913. During this period, 298 patients were under treatment in the home.

NEW YORK.

TWO CENTENARIANS.—Abigail McLean, who died on Jan. 12, at Battenville, near Troy, N.Y., is said to have been born in 1812.

Mrs. Nora Sullivan, who died on Jan. 17, at Potsdam, N. Y., is said to have been born in 1804 at Cahirciven, County Kerry, Ireland, and migrated to the United States in 1838. For the last eighty years of her life she was a habitual user of tobacco. Her health was always excellent.

TWO MORE CASES OF TYPHUS.—On Jan. 17 a case of typhus fever was discovered in this port aboard the Austro-American steamer *Belvedere;* and on Jan. 19 another case was found on the *Kaiser Franz Joseph,* recently arrived from Adriatic ports. The patients were removed to the Swinburne Island hospital, and the vessels and 149 steerage passengers were detained under observation at quarantine.

APPOINTMENT OF DR. BIGGS.—The appointment of Dr. H. M. Biggs as state health commissioner, recently made by Governor Glynn, has now been unanimously confirmed by the state Senate. He succeeds Dr. Eugene H. Porter, a homeopathic physician, who was appointed commissioner by Governor Higgins in 1905 and reappointed by Governor Hughes in 1909. The position had previously been tendered to Dr. Biggs by Governor Sulzer, but he declined the offer on the ground that the conditions attending it seemed to him unsatisfactory. Under the new health law enacted last year, however, the provisions of which were drawn up by a commission of which Dr. Biggs himself was chairman, the state department of health was reorganized with greatly increased powers.

A GALACTAGOGIC SERUM.—It is reported from Ithaca that in the section of the Cornell University Medical College located there a pituitary serum has been evolved which when injected into the circulation of goats has the effect of doubling the quantity of milk produced, while the cream content of the milk is increased fivefold. It is purposed to test the serum next on the cow.

THE AMERICAN SCHOOLBOY.—At a dinner of the Schoolmasters' Association, on Jan. 16, Dr. Charles L. Dana, the neurologist, discussed the question, "Is the American schoolboy overworked and likely to break down under the tasks at present imposed upon him?", and answered it most emphatically in the negative. So far from being overworked, he said, the schoolboy was not even educated, and in his thirty years' practice he could remember only one who was overworked; while in this instance the boy had weak eyes, and this was the principal cause

of his trouble. He did not know of any class of human beings who found themselves less overtaxed mentally, unless it was the college students. Assuming that boys were not either broken down or educated, but were two years behind in the educational race, and since, in the Binet-Simon scale, children, if three years behind in mental age, while in an American college this mental retard was as a rule increased, rather than lessened, it followed that our American graduate belonged to the class of feebleminded, as measured by the Binet-Simon or any other intellectual test. The European idea was that after the age of ten the child was able to do hard work, and ought to be made to do it; the American idea was that he was able to do some work, and should be persuaded to do it. Dr. Ira S. Wile, of the Board of Education, agreed with Dr. Dana that children were not mentally overworked, but expressed the opinion that the medical profession was largely responsible for the prevalent belief that there was danger of breakdown from intense work.

CHILDREN IN MUNICIPAL HOSPITALS.—On Jan. 16 the hospital investigating commission presented a report to the Board of Estimate and Apportionment in which it was recommended that some radical changes should be made, as regards children, in the municipal hospital system, especially in view of the fact that under present conditions many children become infected with diseases which they did not have when admitted to the hospital. Among the recommendations was the establishment of a more adequate children's service at Bellevue Hospital, Manhattan, and at the Kings' Hospital, Brooklyn; at both of these institutions, it was argued, advantage could be taken of the highest class of medical and surgical attendance which would be afforded by their visiting staffs.

MEDICAL ASSOCIATION OF GREATER NEW YORK.—At the annual meeting of the Medical Association of the Greater City of New York, held on Jan. 19, Dr. T. S. Southworth was elected president; Dr. Isaac Hartshorne, treasurer; and Dr. F. H. Daniels, a member of the Council. Dr. Thomas Darlington was re-elected chairman for the borough of Manhattan, and Dr. L. H. Moss chairman for the borough of Queens.

APPOINTMENT OF DR. GOLDWATER.—Dr. S. S. Goldwater, superintendent of Mount Sinai Hospital, has been appointed by Mayor Mitchel commissioner of health, to succeed Dr. Lederle. Dr. Goldwater was graduated from the University and Bellevue Hospital Medical College in 1901, and has been connected with Mount Sinai Hospital since 1903. In 1908 he was appointed medical expert in hospital construction to Bellevue and Allied Hospitals, and he is also advisory expert to the New York Hospital, the Presbyterian Hospital and other large institutions. He is now president of the American Hospital Association, one of the vice-presidents of the New York Academy of Medicine, secretary of the Associated Out-Patient Clinics of the City of New York, and an honorary member of the British Hospitals Association.

TUBERCULOSIS PREVENTORIUM.—The annual meeting of the Society of the Tuberculosis Preventorium for Children was held on Jan. 20. It was announced that $10,617 had been subscribed for the new open-air school building, and the president, Dr. H. M. Biggs, stated that nearly $2,000 was still needed for the completion of the work. The capacity of the institution has been increased from 44 to 158 beds, and as the average length of stay is three months, it is now possible to care for some 600 children during the year.

PHYSICIANS' ECONOMIC LEAGUE.—At a meeting of the Associated Physicians' Economic League held on Jan. 20, a new branch, taking in the upper west side of Manhattan was organized. The special object of the league is the correction of hospital and dispensary abuses, and the president is Dr. Thomas Dixon of Brooklyn.

INFANT WELFARE STATIONS.—The December *Monthly Bulletin* of the State Department of Health is largely devoted to infant welfare stations in the state, giving detailed accounts of the work which has thus far been accomplished outside the City of New York, and setting forth the necessity for its further development, especially in the rural districts.

RECENT DEATH-RATES.—It is announced that the annual death-rate in the state for 1913 was 14.9, as against 14.8 in 1912. With the exception of the latter year, however, this rate is the lowest ever recorded, and the average mortality was less in the cities than in the rural districts.

8. MEAD, F. H. *Persistent Hiccough.*

2. Ten Broeck makes a preliminary report on a study of *achyla muscaris*, a thallophytic fungus, in the treatment of diphtheria. He finds that this organism has the power of destroying the diphtheria bacillus in culture and in the throat and that it inhibits the growth of a number of throat pathogens. It favorably influences membranous anginas of various origin, and is of prophylactic value when growing in the throat. Inoculations are usually self-limited and the procedure is harmless. Mild antiseptics, however, are advisable as after-treatment.

6. Finch reports results with intraperitoneal injections of ozone in animals following injections with virulent bacteria. He finds that this procedure following general peritoneal infection may be without harm to the animal if the concentration is not greater than 0.001% by weight and in oxygen dilution. The use of stronger concentrations produces symptoms other than those due to the physiological action of oxygen, and is dangerous to life.

9. The Public Health Council's report on the typhoid fever epidemic in New York in the autumn of 1913 is interesting reading. Among other things, it contains a striking comparison of the typhoid death rates in European and American cities. In Berlin the rate is 3.5 per 100,000 population, in Hamburg 2.5, in London 4.0, in Vienna 4.1, in Paris 6.7, while in New York and Boston it is 11.6, in Chicago 13.7, Philadelphia 17.4, and Washington 23.2. 3. Wolbarst believes that universal circumcision is a measure of decided benefit and that the objection that it is sometimes followed by tuberculosis or syphilis is not the fault of the operation but of the operator. It is a great aid to cleanliness, is a decided prophylactic against infection with syphilis and chancroid; it prevents in great measure the development of venereal warts, herpes and other growths; it offers a diminished tendency to masturbation; it diminishes local complications in the presence of venereal disease and prevents phimosis and paraphimosis.

5. Meyer makes an artificial esophagus from a portion of the greater curvature of the stomach, which he forms into a hollow tube and leads upward from the cardiac end of the stomach to have its exit at the root of the neck.

9. Wilson states that practically all cases of clinically true exophthalmic goiter show marked primary hypertrophy and hyperplasia of the parenchyma of the thyroid gland. In about 80% of cases the clinical severity can be accurately told by the pathological examination. In simple goitre there are marked degenerative changes present.

10. Smith suggests faulty metabolism of iodin as the reason for the toxic symptoms of goiter.

11. Extracts of exophthalmic goiters cause a very marked fall in the blood-pressure of the dog, with splanchnic dilatation and slowing of the pulse. The first injection produces tolerance toward subsequent

injections. The serum of patients at the height of intoxication from acute exophthalmic goiter causes a marked fall in blood-pressure. Apparently the same depressive substance is present in the blood of individuals suffering acutely from this disease.

3. The authors examined the blood of about 50 cases of tuberculosis, including three cases of the miliary type, for tubercle bacilli. In no case were they able to find them. In many cases they found by microscopic examination, acid-fast bodies but these did not resemble tubercle bacilli in either morphology or color. A specimen of every blood examined was injected into animals, none of which developed tuberculosis. The authors conclude that tubercle bacilli seldom enter the blood stream, and that they remain in it as virulent organisms but a short time.

4. Stern found tubercle bacilli, virulent for animals, in 68% of a series of lupus cases. He comments on this source of infection.

2. Abderhalden states that over 600 pregnancy tests have been made in his laboratory by the optical and dialysis methods with only one or two errors in diagnosis. To obtain such good results, his technic was followed absolutely. One of the chief sources of error lay in the use of improperly prepared dialysis tubes. The other was due to improperly prepared organ extracts. Abderhalden quotes a series of experiments to prove that traces of blood in an organ will sometimes give non-specific readings, which he believes are due to the presence in the serum of protective ferments against blood constituents. If the blood is removed, non-specific reactions do not occur.

3. Baetge has treated four cases of tertian malaria by neosalvarsan injected intravenously. Each patient was given .9 gms. of the drug, repeated in two cases after a week. In each case the parasites disappeared from the circulating blood at once. In one case a relapse occurred after twenty-seven days. No organisms were found again in the other cases after periods of observation lasting from four weeks to two and a half months.

Baetge concludes that the salvarsan treatment of malaria is of value, not to replace quinine but in affording a means for saturating the parasites instantaneously with a destructive agent.

3. To determine the relation of the internal secretion of the thymus and ovaries to the blood constit-

nents, Hermann has removed these glands in a series of young rabbits, making differential and white blood counts before and after operation. To obviate error as far as possible the blood was taken at the same time of day and in the same relation to meals. At later intervals thymus or ovarian extract was injected intraperitoneally and the blood count followed.

In those animals in which the thymus was removed, a fall in the number of lymphocytes occurred, increasing when the gland extract was injected. On the other hand, in the ovariectomized animals the lymphocytes increased, falling when ovarian extract was injected.

Hermann concludes from these observations that the internal secretions of the thymus and ovaries work antagonistically on the blood picture, the thymus setting free substances which stimulate the production of lymphocytes, and the ovarian secretion diminishing these blood elements.

9. The apparatus described by Weiss consists in a graduated cylinder, at one end of which are two bulbs divided by rings into three parts. Diluted urine is poured into the lower bulb to the first mark; a mixture of saturated iron alum and nitric acid to the second mark, and deci-normal ammonium sulphocyanate to the third mark. The mixture is shaken, causing a dark red color. Deci-normal silver nitrate is then added drop by drop, and the tube shaken constantly until the color disappears. The amount of silver nitrate necessary to cause this is read on the graduated cylinder and gives the chloride value in milligrams per cubic centimeter of urine. The results quoted by this method, as compared with Volhard titrations, are sufficiently accurate for clinical purposes. [R. F.]

1. This is a long symposium, given at the Charité Clinic in Berlin, on the Friedmann treatment, and is especially interesting here as showing that in his own country Dr. Friedmann is not held in so much disrepute as here. Five of the speakers, including Friedmann himself, are ardent supporters of the Treatment, while the director of the clinic is, as will be seen, neutral.

Prof. C. L. Schleich (Berlin) eulogizes this method most highly, showing favorable results as proved by Roentgen plates, and concludes by saying "we have at hand a new weapon with which to fight tuberculosis." Prof. Erich Müller of Berlin gives reports of eighteen cases of both surgical and pulmonary tuberculosis, each one showing either marked improvement or entire healing as a result of the Friedmann injections. Dr. Hans Thalheim (Berlin) quotes the histories of sixteen more cases, all with equally favorable results. Dr. Immelmann (Berlin) corroborates the statements of the above from observations he has made on x-ray plates taken before and after treatment: and Dr. Friedmann says a few words about his good results.

Dr. Kraus, head of the Charité, said that the hospital staff were entirely neutral and unprejudiced; that their own cases had not been observed long enough to allow them to draw conclusions; that he had, however, seen one case improve markedly following the treatment, though he himself had advised against it; and that in conclusion he thought this method was harmless and should be given every opportunity to prove its worth—or worthlessness.

It seems clear that many of his own countrymen are by no means convinced that Friedmann's treatment is without value.

9. This is a new preparation of atropine which the author has tried out clinically with pleasing results. It is less soluble and more easily crystallized than atropine sulphate—compared with the latter it shows also less local reaction at the site of subcutaneous injection. It does not cause so much dryness in the mouth and throat, so much acceleration in the pulse or hyperexcitability as atropine sulphate. After citing a number of cases, Philippstal emphasizes its efficacy as an unusual therapeutic agent in asthma, vagus-neuroses, certain tachycardias, night sweats in phthisis and iodism.

[R. H. M.]

Obituary.

SILAS WEIR MITCHELL, M.D., LL.D.

DR. SILAS WEIR MITCHELL, who died of influenza on January 4, at Philadelphia, was born of Scottish ancestry in that city on February 15, 1829, the son and grandson of a physician and one of a family of nine children. His great-grandfather was the "Mr. Mitchell, collector of exise at Dumfries," who was an intimate companion and patron of Robert Burns, and to whom in 1796 the latter addressed his familiar poem, "Friend of the Poet, tried and leal."

Silas Weir Mitchell obtained his education at the University of Pennsylvania, and in 1850 received the degree of M.D. from the Jefferson Medical College. For ten years after graduation, young Dr. Mitchell devoted himself to general practise, and to the pursuit of topics of medical research. He made a special study of

the chemical nature and toxic action of snake venom, and in 1860 published his first monograph on the "Venom of the Rattlesnake." From his father he had inherited a taste and talent for letters, and during this early period devoted much of his leisure to literary as well as scientific study and writing. It was during this decade also that he made the acquaintance of Dr. Oliver Wendell Holmes, who is said to have praised Mitchell's verse as well as his already admirable prose style.

In 1862, Dr. Mitchell was commissioned assistant surgeon in the United States' Army, and was stationed at Turner's Lane military hospital in Philadelphia in charge of soldiers with nervous disorders and wounds involving the nervous system. In this position he served till the close of the Civil War, and from his experience collected material for the publication in 1864 of his second medical monograph on "Gunshot Wounds and Other Injuries of the Nerves." As a result of this experience also he became particularly interested in diseases of the nervous system, and on resuming private practice in 1865 was led to select neurology as his specialty.

Of Dr. Mitchell's eminence as a neurologist, it is needless to speak, or of the many scientific papers and books which he produced during the succeeding years of his busy professional career. Probably he is most noted for his method of the rest treatment of neurasthenia, the theory of which he developed in "Wear and Tear," "Fat and Blood," and other publications. Altogether about 140 titles attest his indefatigable industry in medical research and composition.

Dr. Mitchell's entrance into the field of literature began with the publication in 1863 of his first short story, "The Case of George Dedlow," in the *Atlantic Monthly*. From that time till the last year of his life, Dr. Mitchell was almost constantly engaged upon some literary work as a recreation, entirely apart from his practice and professional publications. His first novel, "Hephzibah Guinness," was published in 1880; his most famous, "Hugh Wynne," in 1897; his last, "Westways," in 1913. Altogether his literary productions amount to some thirty volumes.

Though Dr. Mitchell's reputation as a novelist is foremost in the popular mind, he perhaps really attained a higher degree of literary excellence in poetry than in fiction. His verses* on the fiftieth anniversary of the demonstration of ether anesthesia at the Massachusetts General Hospital are familiar as a noble and fitting commemoration of that momentous event. Probably his "Ode on a Lycian Tomb" is his finest contribution to letters, in its classic perfection of form and deep sincerity of feeling.

For many years Dr. Mitchell was physician to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, and was consulting neurologist to nearly all the Philadelphia hospitals. He was professor of neurology at the University of Pennsylvania Medical School, and at one time president of the Philadelphia College of Physicians.

Dr. Mitchell received the honorary degree of LL.D. from Harvard in 1886, from Edinburgh in 1895, Princeton in 1896, Toronto in 1906, and from the Jefferson Medical College in 1910. The University of Bologna gave him an honorary degree of M.D. in 1888. He was a member of the National Academy of Sciences, of the British Medical Association, the American Neurological Association, the American Philosophical Society, the London Medical Society, the New York Academy of Medicine, and the Academy of Science of Sweden, and was a fellow of the College of Physicians in Philadelphia, the American Academy of Arts and Sciences, the Royal Society of Great Britain, the Royal Medical Society, and the Royal Society of Literature. He was a corresponding member of the French Academy of Medicine, the Academy of Sciences of Bologna, the German Neurological Society and the Royal Medical Society of Norway. He also was a trustee of the University of Pennsylvania and of the Carnegie Institution at Washington.

Perhaps the most distinguishing feature of Dr. Mitchell's character was the versatility, which enabled him to win distinction in two great fields of activity. Work was not labor to him; idleness he abhorred; and upon whatever he was engaged he worked easily and with zest. Next to Holmes, Dr. Mitchell has won an enduring place in American medicine and literature. It is likely to be long before another American physician wins equal rank beside them.

Miscellany.

UNITED STATES MORTALITY STATISTICS IN 1912.

THE census bureau of the United States Department of Commerce has recently published its thirteenth annual report, containing the mortality statistics of this country for the year 1912.

"Unfortunately, the mortality statistics do not include the entire country, but only those states and cities in which the registration of deaths is approximately complete. This area, known as the "registration area for deaths," embraced nearly two-thirds (63.2%) of the total estimated population of the United States in 1912, as compared with only a little over two-fifths (40.5%) in 1900. The increase is gratifying, and there is widespread interest throughout the country, especially in the South, in regard to vital statistics. Virginia has just been admitted, as the result of the model law adopted in 1912, and laws of like character are now in operation in other Southern states, namely Kentucky (admitted for 1911), Mississippi, Arkansas, North

Carolina, and Tennessee. Active efforts to secure such legislation will be made in Georgia and South Carolina, as well as in the northern states of Illinois and Iowa, at the next session of their legislatures."

The 22 states now included in the registration area are California, Colorado, Connecticut, Indiana, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, Missouri, Montana, New Hampshire, New Jersey, New York, Ohio, Pennsylvania, Rhode Island, Utah, Vermont, Washington, and Wisconsin.

"The total number of deaths registered was 838,251, corresponding to a death-rate of 13.9 per 1000 population. The rate is the lowest on record, that for 1911, previously the most favorable year, being 14.2. The year 1912 was also unusually healthful abroad, a new loss mortality figure of 13.3 per 1000 being established for England and Wales.

"By sex, there were 459,112 deaths of males and 379,139 deaths of females. The proportion of deaths of infants under one year to total deaths (17.6%) was slightly lower than that for 1911 (17.8%)."

Though notably decreased, tuberculosis still remains "captain of the hosts of death," having caused 90,360 in 1912, or 10.8% of the total mortality.

"Next came organic diseases of the heart, with 86,179 deaths (adding endocarditis). They slightly exceeded tuberculosis. Acute nephritis and Bright's disease (62,267), pneumonia (51,495), congenital debility and malformations (48,596), cerebral hemorrhage and softening (46,797), cancer (46,531), and diarrhea and enteritis of infants under two years of age (42,482). There were 63,385 deaths from external causes, of which 49,775 were due to accident, 9656 to suicide, and 3954 to homicide. The suicide rate (16 per 100,000 population) was slightly lower than that for 1911 (16.2), and is the same as the average for 1906 to 1910.

"Typhoid fever, with 9987 deaths (16.5 per 1000), showed a notable decrease from the preceding year (12,451) and a most gratifying reduction from the average rate for the five-year period 1901-1905 (32). In other words, it has been cut in half in the last decade, although our rate is still high as compared with some European countries."

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE WEEK ENDING JANUARY 17, 1913.

January 9, Surgeon U. R. Webb, detached, Naval Hospital, Olongapo, P. I., to Pacific Reserve Fleet.

P. A. Surgeon J. C. Woodward, ordered to command the Naval Hospital, Olongapo, P. I.

P. A. Surgeon E. O. J. Eytinge, to Naval Hospital, Mare Island, Cal.

January 10, P. A. Surgeon D. C. Cather, detached: Philadelphia Hospital, to Great Lakes Training Station, Ill.

January 12, P. A. Surgeon W. H. Short, detached: Key West to Naval Station, Guantanamo, Cuba.

P. A. Surgeon E. W. Phillips, detached: Marine Recruiting Station, Chattanooga, Tenn., ordered to Naval Hospital, Philadelphia, Pa.

SOCIETY NOTICES.

BOSTON MEDICAL LIBRARY IN CONJUNCTION WITH THE SUFFOLK DISTRICT MEDICAL SOCIETY (Surgical Section).—A meeting of the Society will be held Feb. 4, at 8.15 p. m., at the Boston Medical Library.

Dr. C. A. Porter, "Surgery of the Peripheral Nerves."

Discussion by Drs. W. E. Paul, J. J. Thomas, E. H. Nichols, Harvey Cushing and J. S. Stone.

HORACE BINNEY, M.D., *Secretary.*

MASSACHUSETTS MEDICO-LEGAL SOCIETY.—The spring meeting will be held in Sprague Hall, Medical Library, Boston, on Wednesday, Feb. 4, 1914, at 2 o'clock.

The following papers will be read and discussed:

1. "Two Automobile Cases." Harry M. Cutts, M.D., Medical Examiner, of Brookline.

2. "The Delaney Murder." John W. Pratt, M.D., Associate Medical Examiner, of Dedham.

OLIVER H. HOWE, M.D., *Recording Secretary.*

MEDICAL LEGISLATION AND MEDICAL EDUCATION.—The tenth annual conference of the American Medical Association on Medical Legislation and Medical Education, called by the Council on Health and Public Instruction and the Council on Medical Education, will be held at the Congress Hotel, Chicago, Feb. 23 and 24, 1914.

LECTURE ON PELLAGRA.—A lecture will be given under the auspices of the Graduate School of Medicine on "Pellagra" with particular reference to its prevention, by Dr. Philip E. Garrison, M.D., of the United States Navy on Tuesday, Feb. 3, in the amphitheatre of the administration building of the Harvard Medical School at 5 o'clock. Dr. Garrison is acting as one of the instructors in the Harvard School for Tropical Medicine. The medical profession is cordially invited to attend this lecture.

THE BOSTON SOCIETY OF MEDICAL SCIENCES announces a meeting of the Harvard Medical School Historical Club (William J. Kerr, secretary) on Tuesday evening, Feb. 3, 1914, in the amphitheater of the Peter Bent Brigham Hospital, at 8.15 o'clock.

Program: History of Variola and Vaccination. Dr. Cushing, "Pock-marks in the Twentieth Century." Dr. Francis P. Denny, "An Old Diary of Prevaccination Days." Dr. Rosenau, "Demonstration of Vaccination." Dr. Rosenau, "Life of Jenner." Dr. Farlow, "Exhibition of Jenneriana from the Boston Medical Library." Books, letters, documents.

DR. THOMAS ORDWAY, *Secretary and Treasurer,*
Harvard Medical School.

APPOINTMENTS.

DR. HERMAN M. BIGGS, formerly general medical officer of the New York City department of health, has been appointed health commissioner of the State of New York.

COL. WILLIAM C. GORGAS, M.D., chief sanitary officer of the Panama Canal Zone, has been appointed surgeon-general of the United States Army.

DR. EDWIN HEMPHILL PLACE, of Boston, has been appointed assistant professor of pediatrics in the Harvard Medical School from Jan. 1, 1914.

RECENT DEATHS.

DR. LEMUEL W. FOWLER, of Boston, who died on Jan. 20 at West Stoughton, Mass., was born in New Brunswick in 1854. After receiving his preliminary education on the provincial normal school at Fredericton, N. B., and teaching for a time in the local public schools, he entered the Boston Dental College, from which he graduated in 1884, since when he has been actively engaged in the practice of his profession in this city. He is survived by his widow, by one daughter, and by two sons, one of them also a dentist.

A PROGRAMME OF PRACTICAL MEASURES FOR MENTAL HYGIENE WORK.*

BY HENRY R. STEDMAN, M.D., BROOKLINE, MASS.

THE magnitude of the field of public work in mental hygiene, the manifold ways in which a well-directed and energetic society of this nature may initiate, stimulate and further measures for the amelioration of the condition of the insane and mentally defective, as well as the possible prevention of mental disease, makes one wonder why we should have waited so long for it. Not until recently have we been able to gauge the public interest in this direction, and the result of the exhibits and addresses already given testify to a general eagerness for enlightenment on this vital question.

Although this society is chiefly concerned with the instruction of the community in the prevention of mental disease, another of its stated objects and an equally important one is that of helping to raise the standard of care and treatment of the insane and sufferers from nervous disease throughout the country, and this will be the subject of my address. Much of it is an old story to the alienist.

Considering the very inadequate allowance made by the state for salaries and wages of officers and nurses, the Massachusetts hospitals for the insane have done efficient work in the care and treatment of patients and their regular and diversified employment and in the instruction of nurses. In scientific work they are coming to the fore. Our laws relating to the insane must surely be advanced and serviceable else they would not have been adopted, as have many of them, by other states. But in the adaptation of natural conditions of home life to the insane within their walls through trained visitation and help such as is nowadays, through social service channels, accorded to the sick and invalid poor in their homes, much remains to be done.

We have long held that there is a large field of usefulness open to a resident social worker in the state hospital, lying between the duties of the hospital physician and nursing staff. Social work away from the world seems paradoxical. Nevertheless, the hospital is the only home and "the ward" the only society of hundreds of semi-sane chronic cases, and the misfortune by which they are deprived of family life should not forever debar them from the individual personal attention, regular friendly visits and frequent advice which form the daily round of duties of the trained social worker in outside cases. Visitation by committees of charitably interested neighbors is often urged, but such efforts only touch the surface of the patient's individual interests and needs, however valuable they may be for purposes of inspection. Intra-hospital social work with the individual patient, might be combined with a number of similar duties on the wards and a systematized department of the hospital's activities be thereby developed. Besides regularly visiting and striving to befriend and interest such suitable patients as the physicians may designate, this worker should undertake the proper circulation of the library books and other publications, with which our state hospitals are well supplied, but which are far too little utilized. She might also be responsible for the entertainments and diversions of all kinds enlisting and interesting both patients and nurses in their preparations and soliciting the aid of outside individuals and societies. By all means let us not allow the insane in our institutions to be left behind by the mill and the department store in such "welfare work."

The eugenic field workers now drafted by our hospitals solely for outside disease-heredity investigations are educated, adaptable and sensible women. Their work offers the great advantage of an insight into the home conditions in which patients live and have been brought up. Should not such knowledge be turned to its most beneficent use in enabling the eugenic worker to be a practical help as a social worker, both in establishing friendly relations with the patient while in the hospital and by her familiarity with the family surroundings, protecting him or her from adverse conditions after leaving the institution? Such an officer would be invaluable and should be well paid. In two of the State hospitals the eugenic field worker has already been turned to similar uses, and it should interest all friends of the insane to see hospital activities taking this trend.

Another direction in which the resident social worker may be of service is in visitation in connection with the family or boarding-out system of caring for selected cases from the chronic, harmlessly insane taken from the institutions, of whom small groups are settled in families in the neighborhood of the state hospitals, under state supervision. This department is not much heard of, but has been in operation in this state more than twenty-five years. The number of patients cared for is not far from three hundred. Those who have had charge of the work make no question of its advantage to the patient, the interest of the family in their charges, and the readiness with which suitable families are found to undertake their care. Those best informed believe that a very much larger number —three or four hundred in about each of the eleven state hospitals—could be so cared for and that the extension and full development of the system is imperative. Besides the elasticity of the system the economy to the state resulting from such a provision, because of the fact that no construction will ever be necessary, is a most important advantage. This measure is surely

* Read before the Massachusetts Society for Medical Hygiene, April 2, 1913.

one to be encouraged by this society because of its possibilities in the way of betterment of the mental health of the state's charges.

Another measure which as many will be interested to know has proved of benefit to the health and happiness of hospital patients, is the establishment of summer quarters at a distance. We all know the advantages which follow change of residence in suitable cases of mental disease; similarly, opportunity for a "vacation" from the hospital ward among country or seaside surroundings is a real boon. Occasionally patients supposed to have become doomed to permanent insanity have taken there the first step toward the restoration of their reason, so great is the effect of this change, many have improved and almost all are in some degree the better for it. The state hospitals in Maine, New Hampshire, and a few private hospitals in other parts of the country have summer quarters for this purpose to which they send relays of patients every year. Most well equipped general hospitals have, we all know, convalescent departments far removed from the main buildings. Why should they not be more generally provided for the insane?

The education of physicians in mental medicine is sadly deficient. We are much behind the times in this direction, although clinics for instruction in mental disease have been for many years an important branch of medical training in Germany. At Ann Arbor, however, in Albany, in Boston and Baltimore, there has been considerable progress following the establishment of psychopathic hospitals and wards for mental cases in general hospitals and the outlook is promising. But why should not each state hospital be oftener utilized for the instruction of the local practitioner in his neighborhood? It will be a very long time before any but the largest cities can maintain and profitably conduct psychopathic hospitals, and even they may be far out of reach for many busy physicians. Moreover, the medical and scientific spirit in our hospitals might be much encouraged by the establishment of closer relations between the medical staff of our hospitals and outside physicians. A practical step in this direction would be the practice of holding every year at least, at each of our state hospitals a meeting of the medical society of the district in which it is situated, as a regular custom. At such meetings clinics could be conducted by members of the staff and the affair made a scientific and social occasion. In this way the bonds of professional fellowship between the isolated hospital physician and the general practitioner would be strengthened, the outside physician would receive, a little, but valuable instruction in psychiatry, which he sorely needs and would welcome, and the attitude of the community toward the hospital would tend, through his influence and personal knowledge of the medical work done in our institutions and the way in which they are conducted generally, to become more friendly and appreciative. This has been done, to be sure, in one or two of our hospitals on rare occasions. Might it not well be made a regular annual custom with all? On one occasion of the kind the members of the district medical society, who attended a meeting at the Taunton State Hospital in large numbers, were so much interested in what they saw and learned that the society published for the benefit of its members the papers that were read and the demonstration of the cases that were given. The Central Indiana Hospital does much more. Its staff gives a course of a dozen or more lectures to all physicians of the neighborhood who may wish to come. This is open to them free of charge. The lectures are accompanied by illustrations and clinical demonstrations.*

The value of popular lectures on insanity, also, in connection with the leading medical schools, has been fully demonstrated both in New York City and in Boston, if the size and interest of audiences is any criterion. They should be generally made use of in all the large cities of the country.

The pressing needs of the mental defectives in this state who, especially of late, have been brought to light in such large numbers in schools, prisons, and other institutions, besides those especially provided for their care, will be told by Dr. Fernald, a far better authority than I. Let me, however, add my voice to the general demand that is so urgent for the speedy erection of another institution for the care and training of this class, and heartily endorse, more especially, the plea that he has made for the continuous segregation of the defective delinquent. The stand which he has also taken on the subject of the sterilization of defectives is a sound and most needed *ex cathedra* protest against hasty and, as many believe, hazardous legislation on a most radical step, involving private rights and public morals.

We do not sufficiently realize that there is a large field for practical work against mental disease and disorder which is as yet undeveloped, indeed, scarcely entered upon. It comprises the outside, non-hospital cases, some of them insane, others defective, breaking down or hopelessly weakened in mind and others on the borderland of vice, crime and mental unsoundness. Taking the insane alone, we find that during the past six years between eight hundred and fifteen hundred unrecovered patients have been discharged from the Massachusetts state institutions. All of them, of course, remain at large for a time, most of them for a year or more at least, and the rest finally are returned to the institutions. Making every allowance, therefore, it is safe to say that with this yearly supply of discharged patients there must be from this source alone a constant residue of at least a thousand unrecovered insane persons at large in the community.

* Since this lecture was delivered a clinic in Mental Diseases, given by the Boston Psychopathic Hospital staff on two days in the week, has been established with the object of making that hospital a centre of advanced training of physicians in psychiatry.

In addition, there is a large contingent of cases, a fair proportion of whom are presumably of the milder and more curable forms of insanity, who never reach the hospital at all. In 1904, six hundred and eighty-five physicians, comprising less than one-seventh part of the medical men of the state, reported to the Board of Insanity, in reply to a circular letter, that of the 2428 cases of mental disease coming under their observation, but 55% had been committed to hospitals for the insane, while 38% had been treated at home and the rest elsewhere outside of institutions. Had all the 5280 physicians in the state been heard from, the figures would have been even more impressive as regards the number of insane outside of institutions, even allowing for the duplication of cases.

Now, although through recent legislation the discharge of unrecovered patients who have shown dangerous tendencies is quite closely safeguarded, many of the perhaps harmless remainder in the community also need supervision, some of them treatment and some a radical regulation of their life and surroundings. Fortunately, it has become a rather general practice, which should be extended to all of this class, to discharge unrecovered insane patients on a "trial visit" through the legal provision which allows a six-months' probation, so to speak, within which time they may be either returned to the hospital, should their condition make it necessary, or be finally discharged at the end of that period. This practice is by no means so general in other states as it is in Massachusetts. It might well be one of the first to be uniformly adopted by superintendents of hospitals for the insane throughout the country, and we hope it will be everywhere urged by our National Society for Mental Hygiene. At the Taunton State Hospital it has been the custom for the last four years to require unrecovered patients so discharged to report in person at the hospital once a month. This practice has been attended with gratifying results and no hardship to the patients. On the contrary, they often spend an hour or two visiting their old friends in the wards. They seem to appreciate the advice given them and have been materially aided in passing the trial period successfully and re-adjusting themselves to home life.

Here comes in still another avenue of social service, through visitation of the homes of these patients who are out on trial visits. The social worker, through her familiarity with family conditions and the patient's requirements, should here be most helpful, either in removing disturbing influences and regulating unhygienic surroundings, thereby making the probation successful, or in preventing in season insane manifestations which require the patient's return to the hospital. By her intimacy with the family, she would also be looked upon as an interested friend and thus be enabled to keep in touch to some extent with the after-progress of the case. The Metropolitan District about Boston offers exceptional advantages for social service work for outside cases—of which the Boston Psychopathic Hospital has begun to avail itself—because of the many facilities in the way of charitable organizations to turn to for help in placing and visiting patients. In the case of hospitals farther removed from the large centres, it would probably be of great advantage to have the headquarters of the social workers at these institutions, placing the department in charge of the resident worker.

Now, a few words in regard to the class of cases to which after-care, the main object of social service, chiefly applies. The discharged chronic insane, as I have said, need oversight and regulation of their life, but it is with the just recovered and convalescent insane patient that the greatest good can be done. Social service should not be exclusively devoted, by any means, to those who are still somewhat insane or weakened in mind when leaving the hospital, but, knowing as we do, the liability of relapse in mental disease, it is of the greatest importance that the apparently fully recovered patient should not be again exposed to the disturbing conditions and harmful surroundings among which his attack originated. If such cases can only be started on the right road we shall have taken the most practical and perhaps effective step toward the prevention of mental disease that is available. As we have said elsewhere,* in the matter of prevention of mental disease it is a far cry from theory and advice to practice. The education of the public in matters of mental and bodily hygiene so that it shall be productive of real, perceptible diminution in the amount of insanity in the community is necessarily a very, very slow process. Nor can the physician himself always feel sure of his ground in the vast complexity of conditions, personal and social, general and special, hereditary and acquired, which combine in varying proportion and degree to produce a case of insanity. Moreover, could we be sure of the cause or causes that would invariably bring on an attack of insanity, all know how little the warning would be heeded by people in general.

Therefore, the supervision and protection of those who have recovered or are convalescing from attacks of insanity would seem to offer by far the most promising field for prevention effort. In this way alone can we hope to ward off relapse or prolong the intervals of sanity between attacks that are inevitable, thereby helping to lessen the vast accumulation of insane patients in our institutions, a large proportion of whom have been admitted a second time, or oftener. When a patient has once undergone an attack of insanity we can with some certainty ascertain the unfavorable conditions that have led up to it, and can endeavor to improve them, thereby guarding against a relapse. We then know the individual victims, and have,

* The Charities Review, March, 1899.

at least, an actual, tangible, present situation to cope with in the unhealthy surroundings, disease, poverty and stress-conditions of specific cases. Besides, when once an attack has been experienced, both the patient and his relatives for a time at least, are amenable to advice and direction through fear of a return of the trouble. The observation of the progress of convalescence and recovery from insanity becomes itself a lesson in prevention. It is a critical stage, beset with dangers which call for the most careful precautions in order to prevent a relapse. Nowhere is this more frequently observed than in the case of the individual private patient. The countless pitfalls for the reawakening and weakened mind through the indiscretion of the patient, his relatives, or his nurse, and the safeguards necessary, must impress all physicians to the insane.

It is usual on such a patient's recovery from an attack of insanity to advise a trip or a rest in the country as a preliminary to taking up the old life and occupation at home; in fact, the entire year following recovery is a critical time, within which we can never feel sure that mental health has been solidly reestablished. If these are the perils and needs of the patient in good circumstances, whose means and the solicitude of whose family are of the greatest assistance to him in regaining a firm foothold upon health, how desperately unfortunate must be the insane person who is poor, on his discharge from a hospital with scant advice, if any. He has no one to encourage him or to provide the assistance which he may need during the next month or two, just as, with impaired mental and bodily vigor, he is entering the struggle against the forces of want and distress which brought him to the hospital. The patient of small resources who has been insane has generally lost or exhausted all his means, and months, and sometimes years, have passed during which he has produced nothing for himself or his family. The fact, also, that he has been in a hospital tells against him for a considerable time after his return, owing to the ignorant popular prejudice against one who has been insane, and it is much more difficult for him to obtain employment. Instead of the extra consideration he deserves, he now, for a time at least, receives the cold shoulder.

The hospital for general diseases has its separate convalescents' home, miles distant, perhaps, from the main building. Of the very numerous homes and retreats for this purpose at the command of charitable organizations of different kinds, not one is for the insane. Convicts on their discharge from prisons and reformatories have long been aided and encouraged by societies for their relief, while for the insane patient who has suffered through no fault of his own there is no provision of the sort in this state to guard him against the return of a malady, recovery from which is in every sense far more difficult than from any other disease. There are, to be sure, states blessed with charitable laws, where patients are given a new outfit of clothing or perhaps a sum of money on leaving the hospital, but this is the utmost they receive. There are few institutions, moreover, where it is the rule even to give precautionary advice to departing patients and their relatives. They receive at best a few general directions, while it oftener happens that their discharge is unknown to the physician except by report. A renowned French alienist and humanitarian, Dr. Giraud, states that he considers the fundamental principle of "after-care" to be the following:—"Society has not fulfilled its duties to the insane when it has helped them to be provided for and treated in asylums if, on their discharge, it leaves them without support and without resources, and exposes them to causes of relapse." He also adds the obvious argument that we have repeatedly urged, that "this is an omission not only from a humanitarian, but from an economic point of view."

This is not a work of such magnitude as it would appear to be. It calls for a week or so of inspection by an agent of the after-care-association, if one be formed, or a social worker from the hospital who shall make sure that the home surroundings are suitable, provide situations and other material help, if need be, for all needy patients, etc. There should be a systematic supervision of the homes and regulation of the family conditions there existing until the patient is so settled that he starts upon his life and work under good auspices. New York State for several years has had after-care associations in connection with a number of her hospitals and much good is done. It is unfortunate that our own state, whose alienists brought the "after-care" project to the front in this country years before social service for any purpose was advocated should have waited so long to put into practice. The great expectations in this direction that have long been held out in connection with the outpatient department of the Boston Psychopathic Hospital seem now about to be realized, but we should not wait for its development there—the work might be equally well taken up at all our state hospitals. Thus far the social service department of the Massachusetts General Hospital and, notably the Boston Dispensary, have alone made any attempt in this direction although in a very limited field. There has been no coöperation on the part of our state hospitals. It should be one of the principal activities of this society to extend social service to discharged insane from our institutions. If it should be thought wise for the state to take up the work, it should have the hearty coöperation of this society.

Finally, there is a most important line of mental hygiene work which cannot be said to have really seen the light in this country, and I must here renew my plea for the establishment

of charitable sanitaria for the cure or relief of sufferers from nervous diseases who are poor or of moderate means and who are not insane. Years of neurological dispensary work among the poor have convinced physicians so engaged that nervousness, neurasthenia, hysteria, psychasthenia, etc., are quite as prevalent among the indigent as among the well to do. These patients are not insane, but without proper care may easily become so, while under suitable care they may be reclaimed and become useful members of society. The deplorable situation in which sufferers of this class from purely nervous diseases find themselves must surely appeal to us all, but there is no sanitarium in this country, (so far as can be ascertained by a careful inquiry of the leading neurologists living in the larger cities) in which poor or indigent nervous cases in any number can have the exclusive care and prolonged treatment that their malady demands. This great need has long been the subject of complaint among neurologists. In this lack of means for thorough hospital care and treatment of public cases coming in its special line of work, neurology is sadly conspicuous among the departments of medicine generally.

To be sure, there are public dispensaries, polyclinics, and even wards of hospitals which are devoted to the treatment of such patients. But they are very far from being adequate. The chronic nature of nervous malady makes the medical relief obtainable through the short stay, the routine prescription and the advice there provided, of slight and evanescent benefit in many cases. The prime requisite for their improvement is, as we all know, removal of the patient from disturbing influences and environment,—from the emotional conditions bred by anxiety and misery in the struggle for his daily bread. But even this is of little avail unless ample time be given for rest and recuperation. That the few days or weeks that answer for the physical and mental relief of other diseases are of little avail in this class of cases, and that disease which has been long in coming on will be slow to leave, have long been the axioms with which we confront the nervous invalid who is in better circumstances.

A certain number of the poorer unfortunates are sent, after a vain search for better quarters and refusal of admittance on all sides by other institutions, to homes for incurables or convalescents where they may, perhaps, remain a little longer, but where it is impossible for them to obtain what they most need,—the medical advice of physicians, both visiting and resident, who understand such special morbid states and know how to combat and either renew or relieve them. General hospitals are not equipped or adapted for their care, and interest in their special treatment is lacking. There are also wards exclusively for nervous cases in a few general hospitals, but except for the opportunities they afford for clinical teaching they are little better and for the same reasons. Moreover, no cure can be effected in such cases without attention to the details of every day life. This is impossible in a general hospital ward. What such patients need is separate institutions or sanitaria, specially constructed and equipped, where they can have the intelligent technical care that their disease necessitates and treatment for the weeks and months that such cases require before they can really improve. Of course, rest must not be pushed too far as the weakened organ requires strengthening and diversified and interesting occupation graded and suited to the strength and other requirements of the individual must be a prominent feature of the treatment. For want of such provision these unfortunates who are often misjudged by the family and friends "go," as Laehr forcibly puts it, "from doctor to doctor, clinic to clinic, healer to healer, in a vain search for what they need." The growing number of private sanitaria for the more affluent nervous patients shows in itself that this is recognized as the only way in which their proper care can be fully attained. They are a boon to the rich, but are for them alone.

During the last fifteen or twenty years the subject of such special sanitaria has also been agitated in Germany where a number have since sprung up while plans for others are on foot. In Switzerland and Sweden also similar sanitariums have recently been established. Does not our knowledge of this great need make it our duty to help meet it? Should we not inform larger circles of the spread of nervous disorders, of the comparative uselessness of the present modes of treatment in most cases, and the loss to the family and society of the working power of these patients?

The class of cases suitable for sanitarium treatment embraces nearly all the forms of nervous disease except epilepsy, for which special institutions are now being gradually provided in the different states. Besides neurasthenia or psychasthenia—hysteria, hypochondria and mild melancholia, migraine, chorea or St. Vitus' dance, shaking palsy, tic, etc., would be found to profit much by an occasional stay in a sanitarium of this kind. Others are the sequelae of apoplexy, cerebral paralysis in children, early paresis of the mild form, and tabes or locomotor ataxia in the early stages, myelitis, infantile paralysis, muscle atrophies, joint diseases, etc. Such an undertaking should be of the nature of a villa colony with a main building for administration and therapeutic purposes—dwelling houses, work shops, agricultural buildings, farm buildings, dairy, granary, etc.

We should all agree with Jacoby of New York, a warm and able advocate of such a provision that the state can hardly be appealed to for aid until the practical proof of its necessity and benefits has been furnished, and it is even questionable whether it would be wise to seek state support in the beginning. The institution

being essentially a charitable one, it will be found that the impressible neurasthenic will be more willing to place himself under treatment, and will do so with greater freedom of mind, if the colony is a private, rather than a state charity. There are, to be sure, many appeals and plans afoot for charitable purposes, and the process of awakening the attention and interest necessary to lay the foundation of such work would be a long and difficult one, in spite of the general knowledge of the increase of nervous disorders; but we have not yet even made the endeavor, and it might well happen that such a charity would strongly appeal to the very class in which the effects of nervous overstrain are particularly prevalent, the "hustling," never-resting business man whose prosperity has been bought at the expense, perhaps of his nervous health. The history of European colonies of this kind, moreover, should lead us to expect with all confidence that ample financial support would be forthcoming.

This list of measures for bettering the condition of the insane and nervous among the poor is a formidable one, but even so, it does not cover all their needs. If, however, this society should each year take up but a single one of them and devote to its furtherance persistent, energetic and united effort, we may feel sure that valuable beneficent results would soon follow.

PRELIMINARY REPORT ON CONTROL OF PERCUSSION BY MEANS OF THE ROENTGEN RAY.*

BY GEORGE C. SHATTUCK, M.D., BOSTON.

Assistant Physician to the Massachusetts General Hospital and Assistant in Clinical Medicine at the Harvard Medical School.

[From the Medical Out-patient and the Roentgenological Departments of the Massachusetts General Hospital.]

HAVING studied this question for a short time only, I am not prepared to add anything to existing knowledge. My desire is to bring out discussion and to stimulate interest in a branch of work which seems worthy of more attention than it has received in this country.

You are familiar with the variations in the size of the heart shadow which are referable, in individuals, to differences in body weight, stature, age, sex, and occupation. You know the three forms of heart shadow which depend chiefly on the shape of the thorax; you know the difference in position of the heart in the sexes, the shape commonly seen in old age, and the changes of position of the heart in the phases of respiration. Besides these differences, there are minor variations, not easy to define, which are comparable to individual peculiarities manifested in other parts of the body; as, *e.g.*, in the face.

It has been maintained by Moritz, Dietlen, Treupel and others that outlines of the heart having a certain degree of individuality can be obtained by percussion, and that these outlines correspond fairly well with those obtained with the orthodiagraph. Dietlen and Treupel have published large series of diagrams from actual cases. Their diagrams show the outline of the heart shadow as determined by orthodiagraphy, and also the outlines of dullness to percussion. Granted that the diagrams have been reproduced accurately and that subjective errors were suppressed as far as possible in their preparation, the following conclusions may be reached, namely, that the heart can in fact be outlined by percussion with a considerable degree of accuracy, that, not only can the three types of normal heart be recognized in this way, but that the outlines are to some degree characteristic for the individual heart.

Before discussing percussion in detail, let us consider the means and methods by which the results of percussion are to be checked. I refer to teleroentgenography and to orthodiagraphy, of which Dr. Dodd has just spoken. It is not necessary for me to compare them. Each has errors and advantages peculiar to it, and there are other errors common to both. Teleroentgenography, being more mechanical and less subjective, is likely on this account, to give the more reliable pictures. The unavoidable margin of error for either method, when skilfully used, is probably below that for the best methods of percussion. It has been stated by others that the unavoidable margin of error for percussion may be 1 cm. That for orthodiagraphy has been variously estimated at from ½ to 2 cm., but it seems likely that, in the hands of experts, the error will seldom exceed ½ cm.

Therefore, it is right that we should control our percussion by means of the Roentgen ray, but it should be borne in mind that no method of comparative measurement of the heart has yet been devised which is truly accurate, and that the results of any method can be accepted only with reservations.

Passing now to percussion itself, let us consider some of the difficulties met with in its use. In the first place, many kinds of percussion have been recommended, and the style of percussion in practice varies much among individuals. Similarly, the results of percussion, that is to say, degrees of difference of note and type of note vary with the kind of percussion, and with the method of using it of the individual percussing. It follows logically that interpretations of these differences of note will not be the same, and, in fact, disagreement among physicians about percussion outlines is so common as to excite no surprise. But, even when physicians outline the cardiac dullness quite differently, it

* Read by invitation in conjunction with Dr. Dodd's paper at the meeting of the American Roentgen-Ray Society. Boston, Oct. 4, 1913.

does not follow that they will disagree as to the presence or absence of enlargement of the heart. On the contrary, I believe that men of experience generally agree substantially in a given case as to the presence or absence of definite cardiac enlargement. Slight hypertrophy of the heart, unless there is some dilatation also, cannot be demonstrated by any method of percussion, owing to the wide limits of variation between the hearts of normal individuals. For the same reason, slight hypertrophy may not be demonstrable in the heart shadow, however obtained.

Treupel compared the results of three types of percussion with orthodiagraphic outlines, from the same patients. He found the very light or "threshold percussion" to be rather the more accurate. He had good results also with the "touch percussion" of Ebstein and with Moritz's modification of ordinary, moderate finger percussion. The heavy type of percussion is being abandoned, and there is a growing tendency to outline both the absolute and the relative cardiac dullness rather than to be content with either alone. They are complimentary when used together, and tend to correct each other. One can go a step further by marking out curves for very slight dullness, moderate dullness and absolute dullness.

We come now to what seems to me the crux of the matter. Three questions arise. First, What changes of note characterize dullness? Second, What degree of such change shall we recognize as dullness? Third, Is the dullness produced by the heart, by the varying structure of the chest wall, or by various other possible causes? We must not be led astray by differences of note other than those characteristic of dullness. We must take into account the fact that the percussion note at a given part of the chest can be influenced by accidental factors such as muscular contraction, and that such factors may produce slight dullness. We should recognize also the following facts which have impressed me more and more, but which, I think, are not always conceded, namely, that the chest of every individual has a more or less individual tone, and that it is difficult to find two areas on any chest wall where the percussion note will be the same, even though the areas chosen be side by side, or at corresponding points on opposite sides of the chest. If any of you doubt this, I hope you will test the statement yourself in a perfectly quiet room, using a percussion stroke just strong enough to elicit audible lung resonance. The variability of note thus encountered is so confusing at times that I occasionally rely more on the degree of resistance appreciable to the plexímeter-finger than on the note itself, and I think that most practitioners use this feeling of resistance in the same way.

Here again difficulties are encountered because resistance varies with the changing width of the interspace percussed, because the costal cartilages run across the interspaces at an angle near the sternum, and because the relative resistance produced by the dome of the diaphragm or by the corresponding upper part of the liver near the base of the lung may mask the resistance due to the heart.

If all differences of note and of sensation have been correctly interpreted, and if an accurate outline of the heart has been obtained by percussion, we have reason to be pleased with our success.

If there is failure in any respect it may be found that we are trying to compare cardiac dullness too literally with a shadow produced by parallel rays, and that we have not allowed for the curve of the chest wall, which often permits dullness to appear beyond the apex of the heart. This apparent error of percussion, when it occurs, is magnified by the thickness of the chest wall when the point determined on the outside of the chest is compared with the sagittal shadow of the heart itself. The discrepancy so produced was emphasized by Moritz, and has been recognized by others. In cases where dullness reaches thus beyond the apex of the heart the error is not one of percussion, but of interpretation of the findings of percussion.

I believe that those who teach percussion are in duty bound to test their methods carefully by means of x-ray examinations, that orthodiagraphy and teleroentgenography can furnish valuable aid to the clinician, and that the advantage of using them has not received the recognition it deserves in this country.

Before finishing, I wish to express thanks to Dr. Dodd for suggesting the work, and to Dr. George Holmes for help in the work and for taking the plates.

RELATION OF FOOT AND LEG MUSCLES TO THE STATICS OF THE BODY.

BY C. L. LOWMAN, M.D., LOS ANGELES

IN an article entitled "The Relation of Thigh and Leg Muscles to Malpostures of the Feet," published in the BOSTON MEDICAL AND SURGICAL JOURNAL, Jan. 18, 1912, I pointed out one of the chief factors causing deviations from the

normal leg balance. Further study and observation have brought to my notice many interesting facts in the relation of foot and leg positions to the statics of the body. This is especially true of its *middle segment*—the pelvis and lower back regions.

In examining and checking up cases of postural strains, or of bad body alignment, in patients with foot ailments, or backache—or both—I frequently find points of tenderness to pressure or motion, in front of the hip joint at the point of attachment of the Y ligament; also along the posterior margin and the upper angle of the great trochanter where the pyriformis and other muscles of the external rotator group are inserted.

We know that any increased muscle pull requires a greater anchorage for the point of origin or insertion of that muscle. Furthermore, that constant tension on a point of tendinous or ligamentous attachment, may excite periosteal irritation and subsequent thickening of the bone at that point. Examples of this condition are found in the exostoses of the os calcis,—either on the plantar surface or where the tendo Achilles fastens—and in the enlargements of the adductor tubercle and inner femoral condyle.

I first noticed in the radiographs of some chronic backache cases, and in other cases of severe malposture, a marked lipping of the posterior angle of the trochanter major—enough in some instances to form a real spur. Then a couple of cases sent to me for suspected hip disease were promptly relieved by proper foot adjustment. Several more cases presenting sciatic symptoms—pain in the region of the sacro-sciatic notch, hip, sacro-iliac area, and lower back—also yielded to the same procedure. I then began to correlate the findings, arriving at the conclusion that the inward rotation of the thigh—throwing the knees out of line and producing or accentuating valgus ankles—was responsible either directly, or as a contributing factor, in the production of these symptoms.

Similarly, I have found in cases of back strain, that a constant tension on the ilio-lumbar ligament had produced, at its points of attachment, a lipping of the vertebral margins and a thickening of the crest of the ilia, accompanied by spur formations. In one case there was almost a complete calcification of this ligament, although the patient presented no symptoms of any osteoarthritic process. She had a loose sacro-iliac joint with a tilting of the pelvis, and a slight rotation of the fifth lumbar vertebra. She was of the relaxed type, and had formerly practiced on the violin four or five hours a day. In other cases in which osteo-arthritic changes were more marked there were findings showing postural defects which had preceded, by many years, a so-called "rheumatic" condition. This is in harmony with the idea expressed by Preiser that mal-alignment has an etiological bearing on later arthritic processes.

It has been my habit in examining and talking with patients to say, "You have two ends to your leg; if one end deviates, something will surely happen to the other end." So with simple pronation cases, valgus ankles, and knock knees, the inward rotation of the leg keeps the external thigh rotators on a tension—particularly the pyriformis. The anterior margin of the great trochanter is, of course, displaced forward. This makes pressure against the structures in front of it. Tension is made, also, on the insertion of the psoas by the rotating of the lesser trochanter inward.

The psoas and pyriformis—two very important muscles connecting the thigh with the vertebral column—are further affected at their upper extremities by the posture usually assumed by patients with weak, flat, or round backs. Measurements made with a pelvimeter will easily demonstrate that the distance from the tips of the spinous processes in the mid-lumbar region to the symphisis, if taken in the relaxed posture, will be much greater than when the patient assumes the correct position with the lumbar curve thrown forward. The increase will vary from one-half to two inches. Thus it will be seen that these muscles are kept pulled sufficiently taut, both at their origin and insertion, to produce irritation at their points of attachment. In a tilted pelvis caused by a short leg, unilateral flat foot, or congenital defect, one would get a similar state of over tension on these muscle groups. In the weak back position, the support of the sacro-sciatic ligaments is slackened by the rotation of the tip of the sacrum forward. This gives the lessened anterior curve which usually accompanies these cases of relaxed posture. Cases of weak or slipping sacro-iliacs, so frequently due to weakened ligaments and loss of tone, are but part of a general mal-posture which includes, also, the foot and leg conditions mentioned before. In such cases, the list of the body is toward the sound side. This gives additional tension to the already tense pyriformis and to the other muscles connecting the thigh with the trunk on the injured side. The condition is further intensified by the loosening of the posterior bony support at the sacro iliac point. This allows the ilium to sag down and to rest, as in a hammock, upon the muscles passing under the notch between the great trochanter and the vertebral column. These conditions, to my mind, account for a great deal of the backache and bodily tire in postural cases, particularly the foot and leg cases. Relief from such symptoms is often brought about by the application of plates and shoes so adjusted as to throw the weight to the outer border of the foot and rotate the os calcis outward.

I think this result is obtained because the knee and thigh are rotated outward, slacking off the muscles above mentioned, giving them a chance to rest and recuperate, thereby reducing the irritation at the points of bony attachment—below

in the region of the hip and above along the lumbar vertebrae. Consequently, I feel that in children and young adults the mere application of arch plates, shoes, and a few corrective exercises applied to muscles *below* the knee are not sufficient to control the actions of the upper end of the leg lever. Such cases should, after necessary rest and the relief from their pain—if any—be given *corrective exercises for the muscles of the thigh and back* if we wish to permanently benefit them, get physiological as well as mechanical results, reduce their leakage of nerve force from the overwork of such large groups of muscles, raise their efficiency for both the present and the future, and insure their latter years against backaches, neurites, disturbances of function in abdominal and pelvic viscera, and probable arthritic changes.

In a short time I hope to add a further report on these observations and shall appreciate criticisms, suggestions, and reports of cases from fellow investigators.

CHRONIC MALARIAL CACHEXIA AND ITS RELATION TO NEURASTHENOID CONDITIONS.*

BY CURRAN POPE, M.D., LOUISVILLE.

Medical Superintendent, The Pope Sanatorium; Neurologist to the Louisville City Hospital, Louisville, Ky.

THERE are few physicians indeed, who are not called upon with varying degree of frequency, to treat the acute and chronic manifestations that arise from an infection of the Plasmodium Malariae.

North of that imaginary boundary, the Mason and Dixon line, the condition ordinarily termed "Chronic Malarial Cachexia" is rarely found, and this is to a certain extent true of a few states in the South. Those of us who are engaged in sanatorial work and who receive a good many patients from the far South, come in contact, with a fair degree of frequency, with these manifestations of chronic malarial poisoning, probably more than practitioners in cities farther North.

These patients usually give the clinical history of a severe prolonged or frequent and repeated attacks of malarial infection.

SYMPTOMATOLOGY.

The skin presents a peculiar appearance. In the majority of cases this alone is very suggestive of chronic malarial cachexia. The cutaneous surface is usually sallow, of a rather muddy-saffron hue, dull and at times dusky looking. It is, generally speaking, dry and harsh, cool or even cold and flushes poorly. There is considerable pigmentation. This condition is much accentuated on the face and hands where the skin has been exposed to the action of sun and air. The palms rarely sweat and the skin reacts very slowly to hydrotherapeutic measures. These patients give one the impression of a person who is suffering from some derangement of the adrenal system. The peculiar *facies* so difficult to describe, but so well recognized by the experienced eye, under the generic term "cachexia" is generally present.

With the rarest of exceptions, these patients present a general leanness, in fact *emaciation* would probably better describe the condition. There is muscular weakness, considerable stiffness with aches about the joints and following certain muscular movements, especially of the back. Under palpation and manipulation the muscles feel flabby, convey to the touch of the examiner a denutritional state that is thoroughly in accord with their complaint of weakness and easy fatigability.

Careful personal observations have taught me that there is nothing more unreliable, uncertain and irregular than the *temperature* of these patients. My cases have ranged from markedly sub-normal, normal, up to irregular temperatures of 100 to 102° F. These observations have been based not upon occasional, but upon careful and persistent daily use of an accurate thermometer.

The *circulation* is almost constantly affected. The heart action is rapid, especially on exertion and cardiac murmurs may be present. I have found quite a number of endo-cardial ones and with fair degree of frequency anemic murmurs. The pulse is usually poor, small, compressible, rapid, with a flabby feeling to the arteries. Its rapidity is quickly increased on exertion. *Blood pressure* readings show a general lowering of both the systolic and diastolic pressures. My observation has been that the pulse pressure is usually in the neighborhood of 20. A great many of these cases complain of cardiac oppression, and palpitation is an exceedingly frequent symptom. The cardiac oppression and palpitation, however, is different in degree and character from that found in the *anxiety neurosis*, being less sharply defined, rather more diffuse and much less intense. It is much worse upon exertion. Usually there is no *angst* accompanying the cardiac and precordial manifestations. An edema of the ankles in the evening is a frequent symptom.

The *gastro-intestinal tract* is *always* affected and oftentimes presents a very prominent symptomatology in the case, these symptoms vary in degree but are present in nearly all cases. Undoubtedly this condition adds to the suffering, discomfort and general cachexia of the patient.

The *tongue* is usually pale, flat and broad, flabby, indented and coated with a moist, white covering, greatest at the posterior portion and occasionally tapering to a point at the tip. I have rarely seen red edges, in fact, pinkness is

* Read before the Ohio Valley Medical Association at Evansville, Ind., November 5-6, 1913.

hardly ever present, the tongue presenting somewhat the washed out and partially shriveled appearance of the "washerwoman hands."

The *breath* is usually foul and suggestive of putrefactive changes in the gastro-intestinal tract. It is a condition that harmonizes well with the appearance of the tongue.

The *appetite* is very fickle, irregular and at times peculiar, but a distinct loss of the desire for food and a tendency toward complete anorexia is present.

Gastric digestion may be encompassed under the term weak. Those cases that do not present a hyperesthetic nervous system, will be found showing a diminished amount of the normal acidity, while the hyperesthetic cases are apt to show a hyperacid condition. In both, however, much more especially the hypoacid cases, a great deal of gas is present and the clinical appearance is that of an atonic state.

The *intestinal activity* is very much weakened.

The *abdomen* is usually distended, the patient complaining of pressure and general discomfort. Constipation may alternate with diarrhoea, but the former has in my experience occurred practically in all cases; the latter rarely.

Fatal hemorrhage has been spoken of, by some authors, as occurring in these cases, but I have fortunately never seen a case of this character. The whole type of symptomatology which the gastro-intestinal tract presents in this disorder, is that of a low grade chronic inflammation. All the gastro-intestinal symptoms are much more marked than in neurasthenia.

Physical examination of the abdomen will oftentimes throw diagnostic light upon these cases and where chronic malarial cachexia is suspected, it would be a grave omission, from a diagnostic standpoint, to overlook a careful examination of the abdominal contents. In most of the cases I have seen the spleen has been enlarged. The spleen is usually indurated and may be so greatly enlarged as to be almost massive, although this is a rather rare condition in my experience. Careful percussion, with the patient standing, will show the spleen area of dullness to be considerably increased and palpation may, in some instances aid in the diagnosis. I have found the *liver* as frequently enlarged as the spleen, in fact, the area of the liver dullness has oftentimes been found to be increased as much as the width of two or three fingers and is, I believe a valuable confirmatory sign. The enlargement of liver and spleen together with the presence of gas in the intestinal tract, tends to make the abdomen prominent.

There is a high grade of *anemia* which corresponds with the patients appearance, which as above stated is usually pale and thin. Of the laboratory findings in these cases, we will have more to say later on.

The nervous symptoms are most marked and are neurasthenoid in character. The term *"neurasthenoid"* is employed, as the writer does not believe this to be a true neurasthenia in the strict interpretation of the term as it is employed by neurologists and psychiatrists today, but that it closely resembles the condition is undoubted and therefore the terminology employed. All mental and nervous symptoms are less in degree than in true neurasthenia. All cases complain of more or less general constant *lassitude*, usually worse in the afternoon and evening, with marked disinclination for physical and mental effort. There is a general disinclination to mental effort, depression, irritability and peevishness and general nervousness, much more marked in the latter part of the day than in the early morning.

In certain male, and in nearly all female, cases there are minor *hysteroid* symptoms with a tendency to emotionalism and a "filling" of the eyes or often actual tears. Subjective *vertigo* is present in certain cases, usually past the meridian of life and possibly due to vascular and toxic conditions. *Insomnia* is one of the most marked symptoms we have to deal with and more closely resembles the true neurasthenic insomnia than almost any other symptom. The patient has difficulty in getting to sleep and is restless until sleep comes. The loss of sleep aggravates greatly the patients condition.

It is a rarety to find cases free from *headache*. This is usually of a dull, heavy character, more often frontal. It is usually worse during the day but does not seem to prevent sleep. It is aggravated by intercurrent disturbances of the gastro-intestinal tract. We do not find in these cases, in my observation, the *"brow-ache"* that is commonly ascribed to malarial conditions. Where *neuralgia* is present, we are more likely to find an active malarial process than a cachexia.

LABORATORY FINDINGS.

The laboratory findings are often interesting, although they may not show any findings that are pathognomonic. The *urine* is usually diminished in quantity; has a higher grade of acidity (35-50); there is diminished urea elimination, unless the patient is rapidly losing flesh. There is oftentimes a trace of albumen, urobiligen and indican. The microscope frequently shows casts and cylindroids, which with the presence of albumen constitutes what the French have very aptly called *"la petite Bright's."* There are usually many epithelia, some from the kidney, but the majority from the bladder. In men we frequently find evidence of prostatic irritation. The *blood* should always be carefully studied. Sometimes its appearance microscopically corresponds with the evident high grade of anemia that is nearly always present, for these patients look the part. The hemoglobin runs low, oftentimes 50 or below, while the red cells are greatly reduced in some instances to close around one million. The microscopic study of the fresh drop will show very pale red cells, many of them distorted although one could hardly say that we have to

deal here with a true poikilocytosis. Oftentimes granules of pigment are found floating in the blood, but more often in the white blood cells. This observation was first made by Manson, of the British Indian Medical Service, and since the publication of his interesting paper, we have looked constantly and searched persistently the blood of these patients for this pigmentation. Lately Wade Brown has shown that the pigment elaborated from the hemoglobin of the red cells by the malarial parasite is hematin. He injected this pigment into the circulation of rabbits and produced a series of phenomena strikingly like a true malarial paroxysm in man. It would seem from this that hematin was the cause of the paroxysm.

We have not found the malarial parasite in the blood with any degree of frequency. Where it has been discovered there have been, as a rule, some acute manifestations engrafted upon the cachexic state. We have often called in question this failure although the blood has been studied under many conditions in the hopes that they would be found.

The *gastric analysis* usually reveals either a decrease or an increase of the acid content, which, as we have said before, we believe to be due to the question as to whether we are dealing with a hyper- or hypo-esthetic nervous system; in the former we would expect to find a hyper, in the latter a hypo-acid condition. A good many cases have a complicating gastritis of low grade, which may, as we well know, accompany either a hyper or a hypo state.

It may not be amiss to state that since the introduction of serological methods, the cases that form the basis of this clinical study have been subjected to a careful investigation along these lines, employing the methods of Noguchi and Weil (Cobra Venom Test) in order that there might be no question as to a syphilitic taint.

DIFFERENTIAL DIAGNOSIS.

The frequency with which these cases are labelled neurasthenia, has led me to be very careful in their separation. The tendency to tag all cases of whatever nature that seem to be generally run down, that have a number of functional (?) nervous symptoms cannot be too heartily condemned. While these cases have many mental and nervous symptoms due to the toxemia of the malarial poisoning, they are not, in the modern conception of the true neurosis, neurasthenic. Neurasthenia as limited today by recent investigation, is an entity (pressure in the head, spinal irritation, dyspepsia with flatulence and constipation, paresthesiae, diminished potency and emotional depression) that the neurologist recognizes as due to conditions other than toxemia. In fact the very careful separation of the true neurosis of neurasthenia and anxiety-neurosis from the many pseudo-neurasthenias that arise from irregularities of the internal secretions, from the various toxemias and other causes, is one that requires no little diagnostic acumen. To have at hand a capacious waste basket into which we may drop our difficult diagnostic problems is undoubtedly an easy solution of the case in hand, but the patient is in the unfortunate predicament of the cat, who is swung by the tail in a room of small proportions. Comfort, at least, is not with the cat. We believe that close *observation alone* would in many of these cases lead the physician to *suspect* what might be the underlying *causus morbi*. Nor should he forget to eliminate hypertrophic hepatitis, Bantis Disease, etc., and any other general or abdominal disease or disorder, merely because of the deceptive appearance of a group of functional (?) nervous symptoms.

DIFFERENTIAL DIAGNOSIS.

MALARIAL CACHEXIA.	NEURASTHENIA.
Skin: Sallow, muddy, dry, harsh.	*Skin:* May be clear, pale, ruddy, flushed, moist.
Palms: Rarely ever sweat.	*Palms:* Commonly sweat.
Skin reaction: Very sluggish.	*Skin reaction:* Very active.
Emaciation: Muscular flabbiness and genuine weakness.	*Emaciation:* Absent. May be fat, muscles and tissues firm, weakness neural rather than physical.
Temperature: Variable.	*Temperature:* Variable.
Heart: Murmurs frequent.	*Heart:* No murmurs.
Pulse: Rapid, small compressible.	*Pulse:* Variable, may be large.
Blood pressure: Lowered.	*Blood pressure:* Variable.
Gastro-intestinal symptoms: Resemble each other but more marked and definite.	*Gastro-intestinal symptoms:* Less definitely marked.
Abdomen: Protuberant, distended.	*Abdomen:* Negative. Ptosis occasionally.
Spleen: Enlarged.	*Spleen:* Not enlarged.
Liver: Enlarged.	*Liver:* Not enlarged.
Anemia: Always present and of severe grade.	*Anemia:* May be present: relatively moderate.
Mental symptoms: Same in both, but less in degree.	*Mental symptoms:* Same in both.
Nervous symptoms: Same in both, but less in degree.	*Nervous symptoms:* Same in both, but greater in degree.
Blood: Pigment: pigmented white cells.	*Blood:* None.
Urine: Petite Bright's present.	*Urine:* Petite Bright's absent.

Recapitulating we may remark that:

1. The symptoms in true neurasthenia, are as a rule, worse in the morning instead of the afternoon; are more of the fatigue and irritative type and more intense than are present in chronic malarial cachexia.

2. The abdominal symptoms enumerated above: these are rarely found in cases of true neurasthenia.

3. The *cachexial* appearance, color and reaction of the skin; an emaciation that is suggestive.

4. The laboratory findings.

TREATMENT.

The success that we have attained in the treatment of these cases has been one of the incen-

tives to the publication of this clinical study. The cases have nearly all been hospital ones, under absolute control as regards their hygiene, diet, rest and the following out of the treatment laid down for the particular case in hand. We mention this as we believe that *hospital* or *sanatorial* treatment and absolute control of the patient are essential for the complete relief of these patients and their return to normal activity. About ninety per cent. were ambulatory, the remainder bed-ridden when the cases came under our observation and treatment. The first step was to lay down hygienic rules as regarded their lives, clothing, rest, exercise, etc. In general they led regular and restricted lives, securing a great deal of rest and especially resting for an hour or longer following the various treatments employed. Weak cases were given modified "rest cure" methods. In all instances, the patients were fed as we would feed them for intense anemia and a low nutritional state, in other words the diet was as fully nutritious and varied as much as possible in order to induce the full consumption of food that the gastro-intestinal organs could take care of, with the aid of gastro-motor tonics and digestants. The endeavor was to increase the quantity and quality of the blood and put fat upon those who were both "lean and hungry;" those who were bed-ridden were treated in bed until able to get up, at which time graduated exercise and a slow resumption of activity was followed out.

During the treatment we have had *acute* malarial attacks to occur, in fact, we are positive that attacks have been brought on by forcible concussion of the twelfth dorsal and first, second and third lumbar vertebrae, by a *very powerful jet douche*. Clinically speaking, we feel that the concussion of these vertebrae produced a contraction of the spleen with a consequent liberation of the malarial organisms and a resulting attack. In several cases we have noticed a malarial attack follow the concussion (mechanically) of these vertebrae and believe that the mechanism of its production is as above stated. If an acute attack supervenes, it should be treated as such without regard to the treatment of the cachexia.

PHYSIO-THERAPEUTIC METHODS.

Massage, both manual and mechanical, is very valuable in the management of these cases, owing to its general tonic effect and its influence upon the nervous circulatory and eliminative organs. As has been known for many years, massage and vibration are reconstructive, largely through their influence upon nutrition and through metabolic changes in the organism. That it has a beneficial influence in these cases can be very readily shown, where we have utilized it as the *sole* mechanical or physio-therapeutic remedy in conjunction with dietetic and hygienic control.

We use *electrotherapy* in these cases: it is an adjuvant but possesses no specific value; is useful in the treatment of certain local manifestations, especially the digestive disturbances and the constipation. Of course, in improving the functional activity of the gastro-intestinal tract and bettering its evacuation, it becomes a contributing factor in the general up-building of the patient. Those currents best suited for these cases are the *galvanic*, using large enough pads to cover both spleen and liver; the *sinusoidal* for its muscular effects upon the intestine and the *static* wave current, per rectum and over the liver and spleen.

Hydrotherapy, we believe to possess a specific influence in this disorder and the results obtained by its use have been such as to lead us clinically to depend upon it as the main weapon in the combat of these cachectic states.

Two classes of cases demand treatment: the bedridden and the ambulatory.

Where the case is bed-ridden, we commence the treatment with a cold sponge at 60-50° F., using a crash glove and secure reaction by vigorous rubbing with a crash towel. As soon as the patient's reaction is well established, we use the dripping sheet at 60-50° F. rapidly applied with good friction once or twice daily. The details of this and subsequently described methods, I have given fully elsewhere.* As soon as the case is up and about, the ambulatory method is employed.

Should a chill develop, the method usually employed is to order hot drinks of either plain or flavored water, lemonade, etc., with hot water bottles to the feet and surrounding the patient or the hot full bath at 102-104° F. for ten to fifteen minutes, followed by rapid drying and lying between blankets; these will give much comfort and shorten the attack. With the subsidence of the chill, we usually wait one hour and if there is no sweating and the temperature begins to rise, we allow the patient to drink freely of cold water and order the cold sponge at 60-50° F. applied singly to an extremity, then to the back and finally to the chest and abdomen, being careful to dry each part as soon as it is sponged and to use a crash mitten or rag in order to produce sufficient friction to dilate the surface capillaries. If, however, the patient should be sweating the parts must first be thoroughly dried after which they are rapidly sponged with very hot water (110-115° F.) the mitten or rag being squeezed dry before being used for the sponging. Each part must be dried and immediately returned to the cover.

If it is believed that a chill is approaching and it is desired to *abort* the attack, the patient should be given large quantities of hot water internally and the hot full bath at 102-104° F. for ten to fifteen minutes and kept warm until the threatened attack has passed.

As soon as the bed-ridden cases are able to get about and for the ordinary ambulatory cases, we employ the following method:

*Practical Hydrotherapy. Cincinnati Medical Book Co.

1. *A hot procedure to perspiration.* For this purpose we can employ the hot full wet pack, the full dry pack, the vapor, hot air, superheated dry hot air or incandescent electric light bath; the latter is undoubtedly, and by far, the best heat measure in such cases, as it acts not only as a provoker of perspiration, but accomplishes this and at the same time stimulates the patient.

2. *A preliminary warm application.* This may be a sponge, the dripping sheet, the hot half bath, full bath, shower, rain, needle, spray or douche.

3. *A cold application.* This may be likewise a sponge, dripping sheet, cold half bath, affusion, shower, rain, needle, spray or douche.

The best all-round combination for ambulatory cases with this disorder, is as follows:—Incandescent electric light bath to moderate or free perspiration, according to the strength of the individual; the needle, rain or shower bath at 102-104° F. for one or two minutes reduced to 60-50° F. for one-fourth minute under twenty to twenty-five pounds pressure, followed by the Scottish jet douche to the spine, (10th dorsal to 4th lumbar) and over the liver and spleen at 105° F. or more under twenty pound pressure reduced to 60° F.,; the alternation should be hot douche one-half minute alternated with the cold douche for ten seconds, three to four alternations.

Following each application, the patient should be thoroughly rubbed and a reaction secured. By reaction we mean the pleasant glow, pinking of the skin and tonic state of the circulation that directly results from the manifold reflexes, etc., that follow the cold application. It is advantageous for the patient to rest quietly after the treatment and to be instructed to drink eight to ten glasses of cold water daily.

MEDICINAL THERAPY.

Most of these cases that come under our professional care have been dosed to death with medicine; have taken calomel, quinine, arsenic, and many other drugs in varying forms and for long periods of time. From our personal experience we would say that very few drugs are of advantage in these cases and that most of them are best employed by the hypodermic method. The first group consists of iron, arsenic and quinine. We prefer to administer iron and arsenic hypodermically daily and believe that there is a certain advantage in giving it in the morning before the hydrotherapeutic measures, as we believe that these favor its better distribution and action, in fact, we are inclined to believe, from clinical observation, that nearly all drugs can be given in smaller doses with better effect and surer physiologic action where hydrotherapy is employed. We believe that iron and arsenic is better in the cachexia than quinine. Where an acute attack is threatened or where one has taken place the hypodermic administration of quinia bi-sulphate in from two to four grain doses will oftentimes spare the patient the nerve racking influence of large doses by the mouth and at the same time be far more effective when given in this way. It is astonishing sometime the beneficial results that come from its use. The other group are the fats of which cod-liver-oil, Sevetol, Russell's Emulsion, butter, olive oil, mayonnaise and a host of other emulsions may be employed. In this connection, it must not be forgotten that real rich milk and cream can often take the place of emulsions.

METHOD.

The methods here enumerated, are as a rule worked into a "system" for each individual case, that is to say the hygienic rules that are to govern the patient are first laid down and explained. The diet is then arranged, the rest prescribed and such medicinal measures as are deemed wise given. The day is divided up so that certain local or special treatments, to meet certain lesions or conditions, such as headache, insomnia, splenic and hepatic enlargements, gastro-intestinal disturbances, etc., and the hypodermics of the drugs used and suggested, given. In the mid-day the hydrotherapy and in the afternoon or evening the massage. In this way we are able to meet many conditions that are clinically indicated in the particular case in hand.

AIM OF TREATMENT.

It will thus be seen that the aim of treatment, as herein outlined, is to:

1. Increase the general neural and vital resistance.
2. Increase the hemoglobin, corpuscular richness and leucocytal activity of the blood, thus overcoming the anemia.
3. To destroy the parasites, at any time should they be present or become active.
4. To increase the elimination of toxins.
5. To stimulate normal metabolic changes.
6. To overcome the neurasthenoid state.

RESULTS.

We have had to deal with quite a large number of these cases and the remarkable success that has attended the method herein outlined has led to the publication of this paper. These patients must be carefully handled and persistently treated. Their cases require time, care and attention, but where this is persisted in brilliant results follow.

It has seemed to us that there are a certain number of cases that seem to possess a peculiar sensitiveness to the malarial poisoning and who have a tendency to develop the cachexia. To these people we advise removal and residence in a non-malarial district and that if this is not sufficient that they be given iron, quinine and arsenic hypodermically and that they take hydrotherapeutic treatment for a number of months until the tendency is entirely eradicated.

A STUDY OF CANCER.—BY SEELYE W. LITTLE, M.D., ROCHESTER, N. Y.

(*Concluded from page 166.*)

TABLE I.

Tissues derived from different germ layers.

ECTODERM.	MESODERM.	ENDODERM.
Entire nervous system.	Blood vessels (except lining endothelium).	*Epithelium* of entire alimentary tract (except anus and part of mouth) and of all glands opening into alimentary canal.
Epidermis.	Bones.	
Hair.	Muscles	*Epithelium* of eustachian tube and tympanic cavity, of trachea and of entire lung apparatus.
Nails.	Connective tissue.	
Enamel of teeth.	Spleen.	*Epithelium* of bladder and urethra.
Epithelium lining. Sebaceous. Sweat. Mammary. } Glands.	Generative and urinary organs (except lining epithelium of bladder and urethra).	*Endothelium* of heart blood vessels and serous cavities.
Epithelium lining nose and part of mouth and pharynx (all mouth in front of pharynx except tongue which is of *endo*dermic origin. That part of pharynx left as remnant of ant. lobe of pituitary is of ectodermic origin).	(Fat probably transformed connective tissue cells,—first appearing in embryo about fourteenth week).	

TABLE II.

Derivation (embryologically) of "ductless glands."

ECTODERM.	MESODERM.	ENDODERM.
Ad renal portion of suprarenals (*that is, the medullary part*).	*Inter*renal portion of suprarenals (*that is, cortex*).	Thymus.
Pituitary body.		Thyroid.
Carotid body.		Parathyroids.
Coccygeal body. ?	Coccygeal body (*probably from medial sacral artery*).	Pancreas, Islands of Langerhans (epithelial origin).
Pineal body.	Testicles (Leydig's cells).	
	Ovaries.	
	Corpus luteum (*epithelial*).	Gastric and intestinal mucosa.
	Interstitial cells (*connective tissue*).	

TABLE III.

Cancer of *mesodermic* tissue occurs only in:
- Generative and urinary organs (except lining membrane of bladder and urethra which are endoderm).
- 18% of all cancers.

Cancer of *endodermic* tissue occurs only in:
- Entire digestive tract with all glands opening into it (except anus and mouth).
- Entire respiratory tract.
- Eustachian tube and tympanic cavity
- Epithelium of bladder and urethra.
- Endothelium of heart, blood vessels and serous cavities.
- 64% of all cancers.

Cancer of *ectodermic* tissue occurs only in:
- Entire nervous system.
- Entire epidermis (including hair, nails and enamel of teeth).
- Epithelium of sebaceous, sweat and mammary glands.
- Epithelium of nose and mouth (except tongue—endo).
- 19% of all cancers.

(Above percentage is from *classified* cancer deaths in New York State for first six months of 1913. There were besides 754 unspecified cancers. Over 8000 per year.)
Above percentages are approximate

TABLE IV.

Six Months' Cancer Deaths in New York. Unspecified.	ECTODERM. (Skin, mouth, breast.)	MESODERM. (Fem. Genital Organs.)	ENDODERM. (Stomach and liver, peritoneum, intestines and rectum.)
1913			
	19		252
	26		116

TABLE V.

Ductless glands presumably mainly at fault in cancer of *mesodermic tissues:*

Derived from *mesoderm.*
- Cortex of suprarenals.
- Leydig's cells of testicles.
- Ovaries.

Ductless glands presumably mainly at fault in cancer of *ectodermic tissues:*

Derived from *ectoderm.*
- Medulla of suprarenals.
- Pituitary body.
- Pineal body.

Ductless glands presumably mainly at fault in cancer of *endodermic tissues:*

Derived from *endoderm.*
- Thymus (in young).
- Thyroid.
- Parathyroids.
- Pancreas (Islands of Langerhans).

TABLE VI.

Conditions often producing hyperglycemia and glycosuria.

Hyposecretion.
- Islands of Langerhans (except in cancer?).
- Parathyroid?

Hypersecretion.
- Suprarenals.
- Thyroid.
- Pituitary.

TABLE VII.

Tolerance for sugar without glycosuria.

Hyposecretion.
- Pituitary. } Ectoderm.
- Sprarenals (medulla). } Ectoderm.
- Suprarenals (cortex). } Mesoderm.
- Ovaries and testicles. } Mesoderm.
- Thyroids. } Endoderm.
- Parathyroids. } Endoderm.
- Islands of Langerhans (in cancer?). } Endoderm.

It is interesting to notice, counting the thyroid and the parathyroid as one system, that for each blastodermic layer there are two ductless glands one or both of which may be at fault in producing the characteristic tolerance for sugar in cancer patients.

THE CASE FOR RADIUM THERAPY.

BY SAMUEL DELANO, M.D., BOSTON.

(*Concluded from page* 163.)

II. EMANATION.

Internal Use. As we have seen, a radium salt depends for its rayage upon the formation of the emanation and further splitting of this into its chain of decay products, Radium A., B. and C. Emanation, in its subtlety and tenuity almost deserves the name of aura or atmosphere. It is, however, a noble gas, obeys all the laws of gases, but is inert—not affected by chemical agents. An idea of its want of bulk may be gained from Soddy's comparisons. The quantity given off by 30 mgms. of radium would still have to be multiplied by 30 to amount to a bubble of a pin's head size. One billionth of a mgm. of emanation may be recognized with ease, and measured. Nevertheless, it may be manipulated and captured by a mechanism. It can be drawn through capillary tubes, liquefied by liquid air, released again into a vapor in a vacuum and finally forced into a capillary tube by a mercury pump. By means of this imprisonment it may be used for radiation purposes and, bulk for bulk, has vastly more strength than the radium salt itself.

In the tube, however, it cannot do one thing that it can when free, viz., cause radio-activity in other objects; when free, emanation in the most minute quantity will, by its splitting into decay products, produce what is called induced radio-activity—a condition which is dependent upon the emanation precipitating its secondary deposit (Radium A., B. and C.). While emanation itself is a gas and has no chemistry; the secondary deposit is metallic in nature, and though impalpable, may be removed by acids, heat, or even sandpaper (in which case the sandpaper becomes radio-active!).

Emanation, through its powers to ionize gases, is just as good a measure of the activity of radium, qualitatively and quantitatively, as are the rays through the evidence of, the photographic plate, the burn, the phosphorescent screen and the ionization. The secondary deposit, of course, furnishes rays by passing (at various distances of time (minutes) through the decay series Radium A., B. and C. Thus a frog killed by exposure to the emanation will photograph itself.

Perhaps nothing better expresses the ubiquity of radio-activity (emanation) than the Biblical phrase, "In the heavens above, in the earth beneath and in the waters under the earth." Gushing from the earth we have the radio-active waters of the so-called neutral springs, the *wildbäder*, with their powers renowned for centuries. We have the radio-activity of the soil, the atmosphere and the sea water, and in the heavens we know, at least, of the presence of Helium (identical with Alpha particles) in the sun, while the fresh fallen rain and snow are radio-active.

Emanation is toxic to animals, and destructive to vegetable life, but non-toxic to man, and a healthy individual is not affected by a dose to which disease reacts. Thus emanation kills the germs of plants, shrivels leaves, destroys hair, nails, ovary, testicle, coagulates albumen of egg, discolorizes the yolk (destruction of lecithin), but it wields many other influences that evidently cut a large figure in its therapeutic quantivalence.

By its mere presence emanation proves itself possessed of catalytic powers, *i.e.* capacity to start or intensify reaction between two other agents. Thus:—

Air and emanation in a tube—the product is nitrous oxide. (Cf. the synthetic production of nitre from the atmosphere by electricity.)

Oxygen and emanation—the product is ozone

Iodoform and emanation—iodine.

All the various fermentations are actively goaded along *in vitro* by emanation—gastric and pancreatic, glycolytic and diastatic, lactic and yeast. It also stimulates autolysis. Of two pieces of cancer tissue in water, the one exposed to radium emanation decays seven times quicker than the other.

But the activity of ferments in nature's laboratory must be much greater than in a test tube; *cf.* the rapid synthesis of proteids from the food. Therefore a much smaller amount of chemical energy is necessary in the body. Hence the entire naturalness of the conception of small quantities of emanation as an active agent. In this connection, compare the fact that one microgram of adrenalin will affect blood pressure. Every process concerned in metabolism in the body must have its specific ferment. Emanation may be looked upon as a strong (general) ferment. Entering the blood it may be absorbed by the colloids (as it is by charcoal); the secondary deposit (metallic) forms a metallic colloid solution analogous to the colloid solution of the metals. This activates the blood, and in consequence all processes of the body are activated.

Prof. Hertwig finds that the blood and lymph cells and the hematopoietic organs are especially affected by radio-activity. Horsely finds that in the nervous system changes are mostly vascular.

Emanation—How Taken? Emanation may be introduced into the system either by drinking water containing emanation, by inhaling the emanation, by bathing in water containing emanation, or by injection.

When inhaled, much immediately returns with exhalation; it is desirable, therefore, to reduce the cubic space, that the emanation may be rebreathed. Taken into the stomach, a good portion escapes via the portal system, right side of heart and lungs. In a bath the process is again one of inhalation largely—there being consider-

able dispute as to whether there is even a small absorption by skin. By injection intravenously the whole amount gets placed.

It is figured by Lazarus that only one-tenth of the inhalation dose is effective, nine-tenths being lost. The blood can be proven radio-active in a few minutes, and with the usual dose all emanation has disappeared from the system in from two to four hours.

The half period of emanation is 3.8 days, *i.e.* in that time half of it has decayed—after that the process goes on in geometrical ratio till a finality is reached in thirty days.

In the case of radio-active water, as *e.g.* from springs (or water made radio-active by contact with an insoluble radium salt) a rapid loss in emanation is the rule, if it has to be handled or transported. Thus most bottled spring waters are decidedly weak.

But if there be radium in solution, the storing up of emanation follows according to a specific law. If radium is dissolved, the rapidity of the formation of emanation increases in rate. At first the decay is in excess of the evolution of the gas, but gradually the amount evolved catches up, till in a month the amount formed is in equilibrium with the amount split up (decay); from this point on this balance is maintained.

Physiological Action. Naturally the action of emanation could be most readily and accurately studied in respect to its effect on metabolism and on the blood.

1. It increases the excretion of uric acid. An amount of .1 gm. *pro die* can be increased to 1 gm. It ensures uric acid's keeping its soluble form in the blood and thus prevents its precipitation. It promotes the absorption of that already deposited. It increases the secretion of urea and promotes metabolism, increases the respiratory quotient, increases amount of carbonic acid excreted.

It diminishes the viscosity of the blood through the improvement of metabolism and the diminished saturation of the blood with diverse material.

It produces a dilation of blood vessels through the excitation of vaso motor nerves.

Through the influence of the last two factors it effects a lowering of blood pressure, even as much as 20-30 mm. of mercury.

It improves digestive processes by activating ferments and stimulates the whole digestive tract by acting on the nerves of the intestines.

It produces diuresis.

It is a rapid tonic, showing its effect in a renewed vigor and *bien aise,* and in an increased body weight and appetite.

By it the blood is modified as to its constitution. A small dose (of a few thousand Maché units) will cause a hypoleucocytosis, but the diminution of leucocytes will not be permanent beyond a certain point. Sometimes there is a hyperleucocytosis (v. Noorden).

After an injection of radium the red corpuscles are found to increase at an astonishing rate, thus from 5,400,000 to 7,200,000 in half an hour and up to 13,000,000 in seven days.

Therapeutics. The scientific application of emanation to therapeutics has a very decided historical basis of support in the centuries-old fame of certain springs that have since been shown to depend for their virtues on the presence of radium emanation. Even among the mines it was known that workers did not have rheumatism, pitchblende sewed in a sack was a popular cure for headache, and the water a remedy for constipation. The red men in America worshipped the "spirit of the springs" and erected huts about them.

The reputation of the springs converged more particularly on gout and rheumatism, but left room, perhaps not less, for general effects on the system and for the repair of senility and sexual decline.

Since the responsibility for the cures has been laid at the doors of radium, the manner of using the water and emanation has been systematized to a point of high development, and as an outgrowth, clinics for the use of the emanation have been established in innumerable centres. This extension has enlisted the services of many gifted clinicians, so that in the six or eight years past much data has accumulated and results have been authenticated. The names of Gudzent, His, Falta and v. Noorden, v. Neisser, Klemperer, Lazarus, et al., form a galaxy, the brilliancy of which should leave no doubt in our minds of great results secured with radium emanation.

There need at least no doubt attach to the remarkable control of radium over gout and rheumatism, in its very varied manifestations. And it is to be remembered that here radium has been offered the task of conquering conditions that correspond rather well to the inoperable cancer. Rheumatoid arthritis, *e.g.* is a well nigh hopeless disease so far as other therapy is concerned, but many remarkable successes have crowned the use of radium. And so with other chronic joints and arthritises, with the exception of luetic and tubercular.

The nearer the joint is to the subacute stage, the more promise of success, especially if it is at the stage of effusion and periarticular edema; but very chronic joints will show vast improvement, if they have not passed into the stage of absorbed cartilage and organized fibrous tissue. "Before experience," says Klemperer, "I expressed myself as very skeptical of the reported successes of others, but now I can say that radium scores such success as does no other therapeutic measure, in rheumatism." Prof. Falta uses the emanation in acute cases even, and says it is to be preferred to the salicylates.

In gout and rheumatism a curious feature comes to light, viz., the reaction, *i.e.* what might be called the "touching up" through the radium; pain, swelling, fever appear or are emphasized. This must be looked for if doses of any size are used, and indeed it offers the means of "taking

the measure" of a patient. Appearing, it is distinctly favorable in a prognostic light. On account of it, occasionally the treatment has to be interrupted; it appears at a variable time, two days to three weeks. Another phenomenon, "late or postponed healing," was well known in the old days of the springs, before radium saw the light. It has to do probably with the presence in the body of the later members in the decay series — Radium D.-F. — which take months for splitting and the liberation of energy.

The action of radium on rheumatism may perhaps be referred to its bactericidal action, radium having a destructive effect on staphylococci and especially on gonococci (the emanation is especially effective in gonorrheal rheumatism), but its influence over metabolism, its autolytic and antiphlogistic action are not to be forgotten.

In muscular rheumatism and inflammatory conditions of muscle and fibrous tissue emanation acts favorably. A lumbago is relieved by a few doses.

In many nervous diseases emanation has been found very valuable. In all neuralgias connected with neuritis or with metabolism or having a uric acid, gouty, or diabetic foundation, radium emanation is a specific. In tabes, Wachsmann found only four out of nineteen cases not benefited as to pains, while, too, the crises were relieved.

In catarrh of the antrum and frontal sinuses Pick has reported remarkable improvement. So in chronic inflammatory conditions in general, as in the pelvis or the myocardium.

There is no doubt that radium emanation has a well defined soporific influence. This has been emphasized by many observers. It may, perhaps, be ascribed to its influence in widening the blood channels.

To the latter effect may be attributed its control of blood pressure. This ischaemic reaction makes it useful in vaso motor disturbances and constrictive states. In this line comes arteriosclerosis, for which the springs in earlier years had especial repute.

Because of increasing the red corpuscles and its pronounced tonic effect in general, emanation acts highly favorably in simple anemias. Cases, too, of pernicious anemias have been reported cured (one recently by Gudzent, although he intimates a relapse as quite possible).

In diabetes, where it has been much used, observations differ. No doubt its effect seems to reach the proportions of a cure in early cases in younger patients. If diabetes is caused by a deficiency or insufficiency of glycolytic ferments (and glycolytic ferments are well borne by diabetics) the coefficiency of emanation in glycolysis ought to be a factor of benefit. Sanbermann is enthusiastic over results in diabetes, and believes that failures are due to small doses (mentions as low as 10-100 M.U.). Mayer and Eichhorst have reported good results.

As a rejuvenator in senility and sexual decline, v. Noorden is especially friendly to radium; and before radium the baths were much resorted to for such influences.

Emanation certainly corrects many conditions of digestion, as intestinal fermentation; it is also laxative and a remedy for constipation.

Practical Use of Emanation. 1. By inhalation, emanation may be introduced into the system if the patient remains in a room the air of which is heavily charged with the gas. To this end large and costly emanatoria have been erected in connection with radio-active springs, with a reduced cubic space, appliances that care for the oxygen supply and the removal of carbonic acid and moisture (the patients are even electrically (neg.) charged to increase the amount of active deposit collecting on them); a further advantage of such an establishment is that every object about the buildings increases the total radio-activity, having acquired an induced radio-activity through the precipitation of secondary deposit.

2. Advantage may be taken of the law that dissolving a radium salt increases the liberation of emanation. The solution is aged until the emanation is in equilibrium with the radium, after which time the amount of emanation is constant and may be continuously used for inhalation—a current of (washed) air or oxygen being forced through the container and conducted out to be inhaled by any number of patients. This is the most appropriate form for a home-made emanatorium. The amount of radium should be perhaps 2 or 3 mgms. to each individual.

3. An individual inhaler may be arranged and installed in a small cabinet or booth. Here advantage might be taken of the law that, if heated, radium gives off its emanation more rapidly. Thus the solution of the radium salt may be boiled, the steam conducted into a container where, the steam being condensed, the emanation is left, to be inhaled.

4. Emanation by the bath resolves itself into emanation by inhalation. There is a small amount of absorption by the skin (Lazarus), though this point is vigorously disputed. A bath may be made radio-active by introducing an insoluble radium salt or residues containing radium. But it is far better (though more expensive) to add a solution of a radium salt, in which the maximum quantity of emanation has been developed by aging. The escaping emanation is to be inhaled, and to this end the cubic space of atmosphere should be made as small as possible. The active deposit on the body should not be wiped off.

5. Emanation *per os* may be in the form of water made artificially radio-active by contact with an insoluble radium salt. But this water is unstable, and the amount of emanation weakens rapidly. Hence it is far better and more dependable (but costlier) to age a solution of a

radium salt,—get the maximum quantity of emanation and make the dose certain.

Radium by Injection. A soluble salt of radium has been introduced into the system intravenously, in pretty large doses, even up to 1 mgm. The usual dose, however, has been 50-100 micrograms. It may be looked upon as the method of securing intensive or quick action. It offers, however, the advantages of slow radiation because a part of the radium is stored up as the insoluble sulphate in the bone marrow, where its slow and gradual decay makes possible a large and continued radiation of the system. No injurious effects have been noted from this sudden lodging of considerable amounts of radium within the system. The intravenous method has been recommended in anemias, but especially the pernicious form, in general arthritis, and in high blood pressure (which it will immediately reduce).

v. Noorden uses a weak solution (1 mmgm.) in the neighborhood of all joints affected by rheumatism; Czerny uses radio-active salt solution (contact with insoluble salts). Domenichi has injected 50-60 mmgms. into joint, drawing fluid off if necessary, with immediate relief of pain and marked improvement within five or six days. In eight cases of anemia, Ledoux-Lebarde has injected 20 mmgms. per week, with distinct improvement.

Czerny makes injections of insoluble salts into tumors—in this case the resorption of the radium is years in completing itself. Uranium oxide gr. xx-℥i in oil has been injected into the fistulous openings of secondary carcinoma, with healing of the case. Tuberculous fistulae discharging pus have been treated successfully with injections of radiferous water.

Radium Compresses. Fine linen mesh with an insoluble radium salt incorporated (*toile*) is used by the French for radiation purposes. If the amount of radium is large it will gradually destroy the fabric by making it fragile. For this a recent substitution of insoluble salts in asbestos has been proposed.

A small amount of a radium salt or a radium-bearing earth can be imprisoned in gauze and forms a very useful application after wetting. v. Noorden makes this application to all rheumatic joints—scrofulous glands have been so treated. Lazarus calls attention to the fact that most compresses on the market are weak. Gauze soaked in radiferous water makes a good application and may be used for dressing ulcerated surfaces, especially malignant. In tuberculosis both pulmonary and intestinal compresses have been used with marked effect. Eichholtz utilizes clysters of emanation water (the emanation is absorbed and excreted by lungs).

Radio-active Earth. Pitchblende residues have always been much used—even before their radium wealth was known. Sewed in a bag it was a remedy for headache.

Pitchblende is applied in ointment form to psoriasis. Even at this date Arendt prefers, for radiation of uterine cancer, pitchblende residue in a rubber finger cot and reports cases of cure (he prefers the slow radiation of the pitchblende, but also uses radium itself). Radio-active earth occurs naturally, as the well known Fango, found in Italy. With this, packs and local applications are made. So as a residue in mining, radio-active earth is left and contains a considerable per cent. of radium. This makes a most useful application. Mixed with boiling water to a paste, it is spread between gauze and used as a poultice; thus Christides reports a clinic of fifteen cases of pelvic inflammatory conditions in which the earth produced much improvement. It has also been used freely by the French, stirred up in a sitz bath or as a vaginal injection.

As to the theory of local action, we must look to the autolytic or anti-inflammatory action of the small amount of radium. London has reported an ulcer of the arm from radio-active cotton. And action on the terminal nerve filaments suggests itself.

Radium by Cataphoresis. Both the emanation and the active deposit collect on the negative pole—a person charged with negative electricity will gather a greater quantity of active deposit, when in contact with emanation. Knox has charged agar-agar plates with emanation, placed them on surface of a growth and produced a deeper penetration by ionization. This field seems to offer much chance of development. Knox suggests that later we may find substances which, when taken internally, may be made radio-active from the outside.

Thorium-x. Thorium emanation does not spring directly from mesothorium as radium emanation does from a radium salt, but is reached only after the interposition of the intermediate decay products radiothorium—thorium-x. The thorium emanation is given off by this last, and unlike radium emanation, is rare in nature. Strangely enough, however, it was used in medicine before radium emanation, for inhalation in tuberculosis.

Thorium emanation has a very short life, 54 seconds, about the duration of the blood cyclosis, therefore it is in practice not considered directly available for therapeutic purposes. Both Bickel and Lazarus deny that it can be detected in the blood after inhalation. On the contrary, Georgés has reported a clinic with its use, and favorable results after a year's experience.

Thorium-x, however, is a substance which, in solution, may be taken *per os* or introduced intravenously. It supplies a method of radiating the system, the body acting as an emanator, and the nascent emanation being liberated within the system.

But this brings up certain very important differences from the emanation of radium. Sixty-five per cent. of thorium-x can be recovered in the bone marrow and eighty per cent. of the emanation is retained within the body. It is, besides, excreted especially by the intestine.

There is thus the opportunity furnished, in the use of thorium-x, for a very intense radiation, likewise for a very slow and prolonged one. Radium emanation makes a quick passage of the cells because the active deposit (Radium A., B. and C.) takes only minutes in breaking up, while thorium emanation makes a slow passage because the decay products are days in breaking up.

The meaning of this is that thorium-x is intense and cumulative, where radium emanation is not. It may be said then that the activating therapeutic dose of thorium-x is much nearer the destructive toxic dose and that in working with it one is always along the edge of the precipice.

Very high doses of thorium-x have been used (stated as high as 3,000,000 M.U.) but deaths have been reported with hemorrhages into the bowel and internal organs, and a large number of observers warn against its dangers. Thus Georgés in using the emanation and contending (against the opinion of others) that results were highly satisfactory, bases his support of it on its lack of danger, in contrast with the great danger in use of thorium-x. Ledoux-Lebarde and Meseth, both users of it, advise great caution.

The great intensity of thorium-x makes for temptation in the wish to see immediate results. Thus in leukemias the white corpuscles can be enormously reduced in a few days even to nil, it is said (as also in animals, experimentally); and in the same way the red corpuscles can be extravagantly increased in pernicious anemias, but the same thing can be accomplished by radium in more deliberate fashion, and in a perfectly safe way. In a recent clinic, Gudzent, the foremost authority on emanation, in a comparison of radium emanation and thorium-x in gout and rheumatism, reports more favorably on radium and includes a case of pernicious anemia apparently healed by the radium.

Radium emanation, so entirely unique, seems then to offer an extensive addition to our therapeutic resources, and no better doxology could be made for it than that it fulfils the great requisite of *primum ne nocere*.

Clinical Department.

A FATAL CASE OF ENDOCARDITIS DUE TO A GRAM-STAINING FILAMENTOUS ORGANISM.

BY WILLIAM H. SMITH, M.D., BOSTON,

AND

OSCAR RICHARDSON, M.D., BOSTON.

A chauffeur, born in Holland, 32 years of age, with a negative family history, entered the Massachusetts General Hospital, October 19, 1911.

P. H. In 1906 he had rheumatic fever, lasting three months, while a second attack in 1907 confined him to the hospital for four months. The diagnosis at discharge read: "Acute articular rheumatism, subacute arthritis, mitral insufficiency, acute endocarditis, broncho-pneumonia, pleurisy with effusion, enlarged tonsils."

P. I. After leaving the hospital he was well until the early summer of 1911. He spent two years in a machine shop. Since then had had easy work as a chauffeur in winter, and engineer on his employer's yacht in the summer.

Early in the summer of 1911, he began to have dry cough and was easily fatigued. A week before entrance to the hospital, dyspnea became prominent, and this had steadily increased; the edema of the feet and ankles had also increased. For about four weeks orthopnea had been present. He was under observation until his death—a period of seventeen days. During this time he ran a continuous temperature, ranging from 99 to 100; occasionally in the evening reaching 101; his pulse was constantly rapid; from 110 to 120; his respirations ranging from 30 to 35. The heart was enlarged; evidence of endocarditis was present at the mitral and aortic valves. There was a constant leucocytosis present, the white count ranging from 10,600 to 20,500; a moderate secondary anemia persisted, the red cells varying from 2,690,000 to 3,200,000, and the hemoglobins 55% at entrance, reached 75%.

On two separate occasions atypical streptococci were isolated from the blood in pure culture—October 19 and October 29. His urine just before death showed a few granular casts with cells adherent.

The interest in the case lies in a study of the organism, an atypical streptococcus, isolated from the blood during life, and a study of this organism in sections of the fresh endocardial vegetations, and in sections of the spleen and kidneys, where emboli were found, postmortem.

The anatomical diagnosis is as follows:

Acute vegetative endocarditis, of the aortic and mitral valves.
Chronic fibrous endocarditis of the aortic and mitral valves.
Small aneurysmal dilatation of the aorta.
Chronic adhesive pericarditis.
Hypertrophy and dilatation of the heart.
Chronic passive congestion.
Ascites.
Infarcts of spleen and kidney.
Chronic pleuritis.
Acute glomerulonephritis.
Septicemia (a filamentous microorganism).

Bacteriological Examination. The organism is a Gram-positive one and stains by the ordinary aniline dyes.

Morphology. Cultures 24 hours old or less on hydrocele-agar show chains of micrococci without capsules with a tendency toward diplo-formation. Some of the organisms resemble pneumococci except that they are much smaller. Cultures older than 24 hours show many pleumorphic forms including oval and apparently barred forms, together with chains of streptococci.

Cultural Characters. On hydrocele-agar there are minute round grayish-white colonies, very slightly moist. Cultures on gelatine or blood serum are similar to those on hydrocele-agar. It does not

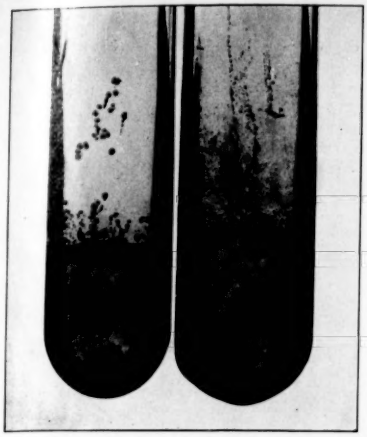

PLATE 1. Twenty-four Hour Growth on Plain Agar.

PLATE 2. Forty-eight Hour Growth from Spleen. Hydrocele Agar. x 1500.

PLATE 3. Valve Vegetations.

PLATE 4. Section of the Kidney. Filamentous Organism in Capillary of Kidney. x 1500.

PLATE 5. Heart Valve Section Showing Filamentous Organism. x 2000.

liquify gelatine. It coagulates milk without gas formation or peptonization.

Carbo-hydrate Reaction. There is no growth on potato. Culture in His's serum water to which lactose, salicin, saccharose, dextrose, mannite, raffinose and inulin are added, show no gas formation in any of these carbo-hydrates but an acid formation in lactose, salicin, saccharose and dextrose.

Hemolysis. Cultures on glucose-agar to which human corpuscles have been added show no hemolysis, even after five-days' incubation, but a gradually increasing dirty greenish zone surrounding the colonies.

Microscopical Examination. Vegetations on heart valve. Masses of fibrinoid material infiltrated by leucocytes and some red blood corpuscles are present; also masses of an irregular Gram-staining filamentous micro-organism presenting spindle-shaped thickenings in some instances.

Spleen. An infarcted area is present. Groups of filamentous irregularly Gram-staining micro-organisms are present. There is hyaline degeneration in and about the follicles.

Kidney. An infarcted area is present. The glomeruli generally show proliferation of their endothelium and some infiltration of polynuclear leucocytes. Small masses of filamentous irregularly Gram-staining micro-organisms are present. In certain of the glomeruli and capillaries they are also found.

In sections of the heart vegetations, spleen, and kidney, this organism apparently is surrounded by a capsule.

We wish to acknowledge the interest in this case of Dr. James H. Wright, and we would express our appreciation to Mr. L. S. Brown for the photographs accompanying the article.

Reports of Societies.

TRANSACTIONS OF THE AMERICAN SOCIETY FOR THE PROMOTION OF CLINICAL RESEARCH, WASHINGTON, D. C.

(*Continued from page 173.*)

RELATION BETWEEN NON-PROTEIN NITROGEN RETENTION AND PHENOLSULPHONEPHTHALEIN EXCRETION IN EXPERIMENTAL URANIUM NEPHRITIS.

Drs. O. Folin, W. Denis, R. Fitz and C. Frothingham, Jr., Boston.

In this work Folin and Denis' method for detecting the amount of non-protein nitrogen and urea in the blood was used. The method is accurate and simple and only requires 2 c.c. of blood. The phenolsulphonephthalein test was done as recommended by Rowntree and Fitz in their experimental work with this and other tests. An acute nephritis was produced in rabbits by uranium nitrate injection subcutaneously and the two tests studied at different stages of the nephritis.

From these experiments it became evident that both these tests for renal function went hand in hand in a general way with the pathological condition in the kidney and with the tests for albumen and casts in the urine.

The phenolsulphonephthalein test is an indication of the renal efficiency at the moment. As the non-protein nitrogen in the blood accumulates gradually the amount of retention is not indicative of the renal function at the moment unless the history of the case is taken into consideration.

DISCUSSION.

Dr. W. T. Longcope, New York: How was the urine from the rabbits obtained?

Dr. Channing Frothingham, Jr., Boston: By milking the bladder.

Dr. S. J. Meltzer, New York: What was the daily amount of urine in these animals? Was it comparable to the normal output? What kind and amount of food was given?

Dr. H. O. Mosenthal, New York: It seems possible to interpret the increase in non-protein nitrogen retention as an expression of increase of protein destruction, as well as of renal insufficiency.

Dr. W. S. Thayer, Baltimore: The introduction of a method by which we may estimate the extent of renal insufficiency is of great importance from a prognostic standpoint. Where, in those cases of impending uremia, we can demonstrate a high percentage of non-coagulable protein in the blood, the prognosis is very grave.

Discussion closed.

Dr. C. Frothingham, Jr., Boston: The experimental rabbits were frequently anuric during periods of high nitrogen retention.

The same food was given all of the rabbits; it consisted of hay and 100 grams of carrots; the rabbits would not always eat all of the carrots.

I do not know the source of non-protein nitrogen, but its increase in the blood seems very definitely to be due to renal insufficiency.

I believe that the estimation of the blood content of retained nitrogen is going to prove of greater value for prognosis than the phenolsulphonephthalein test, inasmuch as the latter test gives reliable information only for the moment.

THE OCCURRENCE OF NUCLEAR PARTICLES IN THE ERYTHROCYTES FOLLOWING SPLENECTOMY.

Dr. Roger S. Morris, Clifton Springs, N. Y.

The blood findings in four patients following splenectomy were reported. It was found that in all four cases examined, nuclear particles were present to a greater or less extent in the erythrocytes. The greatest number found was apparently in a patient thirteen days after removal of the spleen. At this time one hundred and thirty red cells with nuclear particles were found in counting five hundred white blood cells. In a second patient, on the fifth day after operation, there were found twenty red cells with nuclear particles in counting five hundred leukocytes. The two remaining cases were apparently intermediate between these. In one the operation had been done several years previously. In the other, the exact date of operation was not known, but it was said to be a recent case. As the examinations were made on specimens which had been collected for another purpose and as leukocyte counts were not made on the days that the smears were prepared, it has been impossible to calculate

the absolute number of red cells per cubic millimeter which contained nuclear particles. A few normoblasts were found in all four cases.

Roth has reported a remarkable case in which large numbers of nuclear particles were found in the blood three years following splenectomy. Schur in 1908 reported similar findings in a patient who died with pernicious anemia and in whom there was complete atrophy of the spleen.

The nuclear particles are so inconspicuous that they are easily missed in making the usual differential count. To find them when only a few are present, it is necessary to move the slide very slowly, and it is of advantage to use an Ehrlich's diaphragm.

While the number of cases studied is very small it seems possible that the changes described may be a fairly constant feature of the blood of patients who are deprived of their spleen, either through operation or by atrophy of the organ. The findings also suggest an intimate physiological relationship between the spleen and normal hematopoiesis.

The presence of nuclear particles and normoblasts with a normal red count, as in Roth's case, is unusual.

It has been possible to reproduce these findings in splenectomized rabbits. The number of observations is at present too small to determine whether or not the change is a constant one.

DISCUSSION.

DR. W. T. LONGCOPE, New York: With reference to the presence of nucleated reds with a normal count, it is a fact that in cases of lead poisoning there are always to be found nucleated red cells in the absence of anemia.

In the case of two children with cyanosis from cardiac disease, I have found nucleated red cells while the red count was 6,000,000 and the hemoglobin was 90% and 95%.

DR. W. S. THAYER, Baltimore: In this connection it may be of interest to cite a case seen with Dr. Miller, of Baltimore. This was a colored boy with an unaccountable chronic leg ulcer; there was some anemia from time to time; the blood contained nucleated red cells, some of which were marked by chromatic dots. The spleen was not demonstrable by any of the methods of physical examination.

Discussion closed.

DR. ROGER S. MORRIS, Clifton Springs, N. Y.: I am much interested in Dr. Longcope's remarks on lead poisoning; I was not aware of the presence of normoblasts in such cases.

In the cases of cyanosis in which nucleated cells were found, the explanation is probably to be found in the concurrent polycythemia.

Dr. Thayer's case is of great interest in this connection.

ABSTRACT.

SALVARSAN IN PERNICIOUS ANEMIA.

DR. THOMAS R. BOGGS, Baltimore.

The conflicting report on the use of this drug in the treatment of pernicious anemia justifies a brief summary of personal experience and review of the more important previous reports.

Leede's unfavorable results were probably due to beginning too late.

Bramwell's reports have been encouraging.

In our experience with small doses at intervals of four weeks we have seen no unfavorable result attributable to the drug, and some remarkable apparent cures in patients who did not respond to other forms of arsenic.

The experience at the Johns Hopkins Hospital, while the study was less complete does not show any bad results attributable to the use of salvarsan. It is important that this drug be tried promptly in this disease, and especial attention paid:

(a) To the question of syphilis in the patient.
(b) Influence of salvarsan when given alone.
(c) The effect on arsenic-refractory cases.
(d) Permanence of the results.

DISCUSSION.

DR. JOS. L. MILLER, Chicago: I entertain, perhaps, unwarranted pessimism as to any real improvement in pernicious anemia, especially when I have so often seen periods of very marked improvement appear independent of therapy. My experience is that when improvement takes place during the administration of arsenic, thorium, or anything else, a relapse may be expected and when it appears the remedy which was supposed to be responsible for the improvement has no further good effect.

DR. I. ADLER, New York: I must confess to agreeing with Dr. Miller. I have for many years observed a great number of cases of pernicious anemia, and I believe that if such cases are observed long enough it will be found that they are never cured.

I remember one case in which improvement, almost to normal, occurred and was sustained for three years, when the inevitable relapse appeared. No therapy really affects the underlying cause of pernicious anemia, whatever it may be. Those cases that are refractory to arsenic are generally those that can no more be helped by anything.

DR. S. J. MELTZER, New York: May not the effect of salvarsan in pernicious anemia be merely that of stimulation of the formation of red blood cells?

Whatever the mode of action, certainly an increase of red cells from 500,000 to 5,000,000 under exact laboratory observation, indicates a very unusual degree of success in the treatment of these cases, at least. We are all familiar with the type of observations made by Dr. Miller and Dr. Adler, and some of us are old enough to realize the fallacy of depending upon mere therapeutic observations; but Dr. Boggs' studies were controlled by exact laboratory observations and should command thoughtful attention.

DR. H. F. SWIFT, New York: With respect to febrile reactions, much stress was laid upon this feature of salvarsan therapy in the early Hamburg reports, and at that time such reactions were very frequent. But with improved technic of administration, most of these cases can be ruled out now. We have had one syphilitic patient, however, who is persistently fibrile after salvarsan administered with the most careful technic.

DR. J. A. CAPPS, Chicago: The mere fact of the improvement of Dr. Boggs' patients is not so impressive as the fact of the rapidity of the blood regeneration. In most cases the improvement is more gradual; as, for instance, in one of my cases in which the red count rose from 1,000,000 to 4,000,000 after normal salt by rectum, but in which this improvement required two months' time. I can recall

no treatment comparable in rapid results to the method employed by Dr. Boggs.

I would like to ask Dr. Boggs in what proportion of his cases was a syphilitic history obtained?

DR. J. H. PRATT, Boston: Naegeli has found that since the introduction of arsenic in the treatment of pernicious anemia, relapses are much more common. This may mean that improvement is more often noted after arsenic therapy.

DR. W. S. THAYER, Baltimore: We should hardly take Dr. Boggs to mean that he regards salvarsan as a cure for pernicious anemia. He seems merely to be presenting some very striking results obtained by giving this drug in this disease. What was the size of the dose given? Possibly the fear of febrile reactions deterred him from giving large enough doses. If there is any underlying protozoal cause for pernicious anemia, the use of a lethal dose of the drug is important.

DR. T. R. BOGGS, Baltimore: It was not at all my intention to announce a cure for pernicious anemia. The work was undertaken and the results were reported because we so easily get into the habit of letting these chronic conditions alone. I was impressed by the rapid blood regeneration possible in this particular chronic disease, and the cases seem to point out that we are not entirely helpless even when confronted by extreme grades of pernicious anemia.

The dose employed was 0.30 gm. of old salvarsan. All of the patients had febrile reactions and they were rather more severe than one encountered in the treatment of syphilitics. In the very sickest patient the temperature rose to 104° F. and his condition was desperate for a time.

In my own four cases there was no evidence of lues; in the eleven cases from the Hopkins, two were luetic, one having a very severe blood depression and dying in 72 hours.

INTESTINAL SAND. REPORT OF A CASE WITH CHEMICAL ANALYSIS OF SAND.

DR. FRITZ B. TALBOT, Boston:

The writer reported a case in which true intestinal sand appeared in the feces at frequent intervals always associated with digestive symptoms. Unlike the case of Myer and Cook (*Am. Jour. of Med. Sciences*, 1909, Vol. cxxxvii, p. 383), the sand had no connection with the bananas in the food.

The chemical composition was as follows:

Nitrogen	3%
Total fat	5%
Ash	17.4%
Calcium	7.4%
Magnesium	2.0%
Phosphates	present
Material soluble in alcohol after hydrolysis (resinous?)	14%

No discussion.

SOME EFFECTS OF REPEATED ANAPHYLACTIC SHOCKS IN ANIMALS.

DR. WARFIELD T. LONGCOPE, New York.

The experiments were planned to determine if changes in the parenchymatous organs and particularly the kidneys, could be produced in animals by injecting repeatedly in sensitized subjects sublethal doses of foreign protein. Guinea-pigs, rabbits, cats and dogs were used in these experiments. Egg white and horse serum were employed as foreign proteins. Three weeks after sensitization guinea-pigs were inoculated repeatedly intraperitoneally, rabbits intraperitoneally and intravenously and cats and dogs intravenously, at periods of four days to three weeks. In some instances as many as 12 to 14 inoculations were made. After repeated inoculations the kidneys both of dogs and rabbits showed well marked changes consisting in necrosis of the cells of the collecting tubules and loops of Henle with varying degrees of patchy cellular infiltration in the interstitial tissue extending from the mid zone to the cortex. In the animals that survived longest, the cellular infiltration was accompanied by an increase of connective tissue with atrophy of tubules and thickening of the glomerular capsules. In the livers of rabbits and cats there occurred necrosis of liver cells varying in size from the space occupied by a few cells to large portions of the lobule. These were most marked in rabbits. They were usually situated in the periportal zone but occasionally involved the mid zone of the lobule. Together with these areas of necrosis about which the capillaries were open, there was extensive infiltration of small round cells with later new formation of connective tissue in the portal spaces, leading in advanced cases to a picture resembling somewhat a portal cirrhosis in man.

In the guinea-pigs no extensive lesions were found in either liver or kidneys.

These experiments show that repeated anaphylactic shocks give rise in dogs and rabbits to varying degrees of acute and chronic interstitial nephritis, and in rabbits and cats to changes in the liver that result in a moderate degree of portal cirrhosis.

DISCUSSION.

DR. H. A. CHRISTIAN, Boston: As to the possibility that the lesions described by Dr. Longcope may have been spontaneous in origin, from the description of the liver lesions, I do not think it very likely that they were spontaneous.

In my own work with rabbit livers, it is rare to meet with lesions, except in coccidial livers, where the changes are more like hemochromatogenous hepatitis.

It is more difficult to answer the question as regards the kidney, but it may be decided for practical purposes by studying the kidneys of control rabbits from the same stock.

DR. I. ADLER, New York: A number of years ago, I fed chickens exclusively with meat and found lesions in the liver identical with those found by Dr. Longcope in the livers of his rabbits.

DR. C. FROTHINGHAM, JR., Boston: What does Dr. Longcope regard as the primary lesion in the kidney? Is it vascular, parenchymatous, or interstitial?

DR. E. C. ROSENOW, Chicago: Were the rabbits studied by Dr. Longcope old or young? I have found that spontaneous nephritis is very rare in young rabbits.

Discussion closed.

DR. W. T. LONGCOPE, New York: In reply to Dr. Christian's remarks, I would say that I have studied control rabbits from the same stock, and have not found spontaneous kidney lesions; but I have felt that the evidence was not conclusive.

I am not certain where the primary lesion takes place, but I believe the first charges are to be found

in the walls of the capillaries and in the tubular epithelium.

The rabbits used in the experiments were young animals weighing from 1000 to 1500 grams.

Dr. Adler's remarks were interesting and his work was evidently confirmatory of my own.

STREPTOCOCCUS ANAPHYLATOXIN AND HYPERSENSITIZATION OF RABBITS, AND GUINEA-PIGS TO VARIOUS STRAINS OF STREPTOCOCCI.

DR. GEORGE DRAPER.

The object of the investigation was, first to produce an anaphylatoxin from various strains of streptococci and then to produce hypersensitive states in rabbits and guinea-pigs with streptococci.

By using old broth cultures, anaphylatoxins were produced with regularity. The centrifugates of large quantities of the culture were left in contact with fresh guinea-pig serum at room temperature for 24 hours, and the supernatant serum of this mixture, after centrifugation (about 4 cc.) were injected into the jugular vein of a guinea-pig. Typical anaphylactic shock and death in from two to five minutes with typical autopsy findings occurred in all cases in which the above technic was used.

In the hypersensitization experiments the animals were given two or three sensitizing doses—the guinea-pigs, intraperitoneally; the rabbits intravenously—of streptococci heated to 60 for one-half an hour. The amounts varied from the centrifugate of 10 cc. broth culture to 0.05—0.1 gm. (by volume as shown by graduate centrifuge tubes). The streptococci were thoroughly washed in salt solution before injection. Three weeks or more after the last dose the rabbits were given 0.1 to 0.3 gm. intravenously. There were marked symptoms in several cases and death in two. The symptoms had certain suggestive characteristics of anaphylactic shock in rabbits but were not typical. They were severe, however, and similar in all the experiments.

The guinea-pigs had typical anaphylactic symptoms but death was not produced.

There are now in progress control experiments of the phenomena described in guinea-pigs and experiments with the rabbits that have survived the previous injections of large quantities of killed streptococci to determine whether they have been rendered more susceptible to infection with the living organism.

BESREDKA'S METHOD OF PREVENTING ANAPHYLACTIC SHOCK.

DR. R. WEIL, New York:

It is well known that sensitized animals, which have received a sublethal dose of antigen, become anti-anaphylactic. Besredka, therefore, suggested that human beings in whom there was a possibility of previous sensitization should receive a small dose of antigen, previous to the therapeutic injection. The question arises whether Besredka's generalization is justifiable. His results were based on experiments on guinea-pigs, which had received very minute fractional doses of serum to sensitize. He stated that larger primary doses do not sensitize but immunize. As has been described in another article, however, the vast majority of immunized animals may be shown to be typically anaphylactic, provided the intravenous route is employed for the toxic injection. The problem, therefore, narrows itself down to the question whether guinea-pigs sensitized by large doses are rendered anti-anaphylactic by the administration of an intermediate, relatively small, injection of antigen. It was demonstrated by means of experiments both on actively and on passively sensitized guinea-pigs that this is absolutely not the case. In fact, such animals may be given an intermediate injection of antigen which would suffice to kill control animals sensitized by small doses, and still remain anaphylactic. Under certain conditions, they may be even more highly anaphylactic than before. It follows that the intermediate prophylactic injection cannot in sensitized guinea-pigs be calculated in such a manner as to render the animal anti-anaphylactic, unless the degree of sensitization, and the corresponding minimal lethal dose, be accurately known. In human beings, such information is, of course, impossible, and the Besredka method is consequently always unreliable, and at times even dangerous. A case report from the French literature is cited, in which the B. method was employed in a human being, and the subsequent therapeutic injection produced anaphylaxis and threatening death.

DISCUSSION.

DR. R. I. COLE, New York. Does the time relation affect the results?

DR. W. T. LONGCOPE, New York: I have observed about the same phenomena when giving serum intraperitoneally or subcutaneously; at the same time, intravenous injections of rather large doses would produce symptoms. Has Dr. Weil used repeated intravenous injections? I have observed also that repeated small doses will finally produce symptoms.

Discussion closed.

DR. R. WEIL, New York: The period of desensitization does not exceed eight days. In active anaphylactic sensitization the time period has not been worked out. As far as guinea-pigs are concerned sensitization lasts for life.

In reply to Dr. Longcope's question, a moderate degree of protection can be induced for intravenous injections, but it is not absolute.

If in rabbits serum is given every day, there will be no symptoms; if, however, an interval of three or four days is allowed, accidents will thereafter occur.

STUDIES ON THE INCUBATION PERIOD.

No. 2 Concerning Virulent and Avirulent Cow-pox Vaccine.

DR. DAVID MURRAY COWIE, Ann Arbor: In a preceding study of the Incubation Period (No. 1) the clinical phenomena following the injection of horse serum were considered. (Serum sickness.) The present study has to do with similar or analogous phenomena following the introduction of cow-pox vaccine into the body in various ways.

The usual phenomena following the ordinary cutaneous vaccination in the unvaccinated and revaccinated are well known. Theoretically we might expect an earlier take in a revaccine if any take should occur, and experience teaches us in a great many instances this is so. A point that has not been generally recognized is that within 24 to 36 hours after the introduction of living cow-pox

lymph into the skin of an individual previously successfully vaccinated a certain degree of hyperemia results, but does not so result after a primary vaccination and that during the incubation period of a primary vaccination and preceding the development of the papilla a similar hyperemia may be obtained by introducing fresh vaccine into the skin. This we have every reason to believe is an allergic phenomenon and shows that the entire organism has responded to the initial injection.

Virulent cow-pox lymph may be injected in low dilution into or beneath the skin in appreciable amount without inducing general symptoms. Subcutaneously the deep infiltration felt after injection continues for a few days, then gradually disappears. Within 24 hours the body becomes allergic. Intradermal injections are followed in a few hours by hyperemia and nodular formation which persist for many days. The body likewise becomes allergic within 24 hours. Reinjection in either case is accompanied by an almost immediate response. Children subsequently vaccinated by the cutaneous method in the majority of instances fail to react with papilla or pustular formation.

The phenomena following similar injections of avirulent (dead) lymph react differently. This difference seems to be one of degree up to a certain point. High dilutions of lymph from 1-100 to 1-1000 induce the allergic state (but allergy seems to be attained more gradually.) Intradermal injection leaves no nodular formation in the majority of instances. (This depends to a certain extent upon the physical state of the lymph.) No cutaneous reaction follows these primary injections (excepting with very concentrated solutions, when a reaction occurs within 24 hours); re-injection of high dilutions intradermally is followed on the third and fourth day by a cutaneous reaction analogous to the cutaneous tuberculin reaction. The larger the initial injection the surer the subsequent cutaneous reaction. Following successive inoculations of avirulent lymph, in proportion to the total amount injected, up to a certain point, a greater cutaneous reaction occurs. This is analogous to successive horse serum injections. However, all points do not light up as in successive cutaneous vaccination and horse serum injections. No febrile reaction follows the first injection of avirulent lymph in the unvaccinated. On the other hand, if an individual previously successfully vaccinated is given a subcutaneous injection of dead lymph, of certain concentration, he may react with fever, local hyperemia, and nodular formation within 16 hours.

An individual once successfully vaccinated is apparently permanently allergic. That is, he will always react without question to an intradermal injection of diluted avirulent lymph (21 years). An unvaccinated individual who contracts smallpox reacts quickly to an intradermal injection of diluted avirulent cow-pox lymph. The reaction is usually first seen early, within 5 to 10 hours, and may fade quickly. This shows the phylogenetic relationship of smallpox and cow-pox.

From these observations it will be seen that sensitization to virulent cow-pox vaccine is a quick affair, a matter of hours, not days, as in tuberculosis and serum disease; that a greater reaction seems to obtain after a pronounced cutaneous vaccination. Such cases may react in fractions of an hour after an intradermal of 1-100 avirulent lymph.

The infiltration of the tissues of the arm following cutaneous vaccination, revaccination, and reinjection of living or dead lymph is an allergic phenomenon and is analogous to the specific edema of v. Pirquet in serum disease.

Children who have never been vaccinated may be rendered immune to cutaneous vaccination with virulent cow-pox lymph by subcutaneous and subepidermoidal injection of avirulent lymph. In cases which do react after such immunization the subsequent course of the cutaneous vaccination is attenuated.

The incubation period of cow-pox disease is characterized by a very short preallergic stage as compared with serum disease and as recognized by the intradermal test.

In this brief abstract space does not permit of proper reference to the early workers with cow-pox lymph, or of the more recent and highly meritorious work of Knöpfelmacher, v. Pirquet, Hamburger, and their co-workers.

No discussion.

(To be continued.)

Book Reviews.

Geschichte der Ohrenheilkunde. von DR. ADAM POLITZER. Zwei Bände. II Bande. von 1850-1911. Unter Mitwirkung Bewährter Fachkräfte. Mit 29 Bildnissen auf 29 Tafeln. Stuttgart: Verlag von Ferdinad Enke. 1913.

Politzer finishes a monumental career with a most fitting and monumental work,—his "History of Diseases of the Ear." The second volume of this work, a book of 484 pages, has lately appeared. It is divided into two parts, the first dealing with the important advances in the anatomy, physiology and pathology of the ear, from 1850 to 1911, and the second division with the history of the development of otology in the different countries of the world. The text is made up of monographs by various well-known men. The portraits of many of the pioneers in otology are introduced. The history of otology in England is written by Hunt, Birkett writes of Canada, and Blake of the United States.

It cannot fail to be a matter of pride to Americans that the volume is dedicated to Boston and New York, that is, to Professor Clarence J. Blake and Professor Gorham Bacon. The book is practically an encyclopedia of otology, scientific and historical. For years it should hold first place as a reference book. It is hard to see how anyone writing a scientific paper can afford not to consult it in substantiating his data.

The collaborators have been very generous in mentioning their confrères. This is especially true of the United States. In one instance, at least, this good will was carried so far as to give one man a title which fate has not bestowed upon him. The writer hopes that this may be prophetic.

The book is beautifully printed on fine paper. The second part might be called the "Who's Who," or the Blue Book of Otology.

THE BOSTON
Medical and Surgical Journal

THURSDAY, FEBRUARY 5, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: $5.00 *per year, in advance, postage paid, for the United States.* $6.56 *per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 *reprints free, if requested in writing.*

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

A DECENNIUM OF PROGRESS.

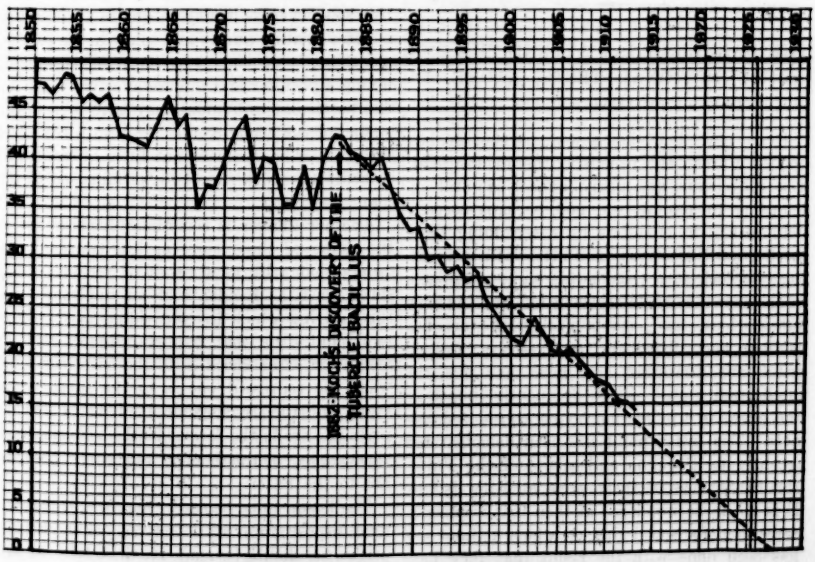
THE November *Bulletin* of the National Child Labor Committee reviews a decade of work to free children from labor in factories, mines and shops. The finest optimism is that which persists in being optimistic despite the greatest temptations and justifications to adopt a pessimistic view of civilization. This committee's experiences would have justified the latter viewpoint, yet its report breathes throughout a confident and optimistic spirit. Much practical accomplishment is recorded, both in legislation and in factory reform; and a summary of child labor legislation shows a much longer list of laws secured than of defeats.

"The committee, organized ten years ago for a short and sharp campaign against child labor, has had to face much disillusionment. Idealists who supposed that if the people realized the truth about child labor they would forthwith abolish it, have learned that public knowledge is not sufficient until it is fired with enthusiasm and guided by active leadership. The National Child Labor Committee has grown in membership and efficiency, and it has been able to advance with ever-increasing momentum against the phalanx of tradition, indifference and greed. But the short and sharp campaign is lengthening into a twenty years' war. However, so long as we continue to have the loyal coöperation of our members, we know that there will be an end to the war, a joyful day when the committee will celebrate its anniversary, not by an appeal for doubling the membership, but by permanently disbanding the forces. Meantime, that day is far distant, and we most earnestly call to the attention of our readers the celebration of our tenth anniversary."

The committee's two most notable achievements are: the adoption of a children's code in Ohio, fixing a minimum age limit for employment at fifteen years for boys and sixteen years for girls; and the enactment of a law in Massachusetts limiting the hours of labor for children under sixteen to eight per day. Massachusetts is the first commonwealth in the world with cotton textiles as a leading manufacture to set so high a standard. The law was strongly opposed, and the factory owners have been threatening to repeal it. The results of such a law have shown that none of the bad effects on industry and public welfare always predicted by opponents have followed. On the other hand, in the North Carolina cotton mill communities, the school attendance is always lower than in the rural or even the mountain districts.

In looking forward to the tenth anniversary (April 14, 1914) the committee records that the child labor laws of all states except two have been improved; that exact knowledge of the condition of working children has been established, together with a recognized standard of protection; and that the federal government has in successful operation the Children's Bureau. The committee has increased to 7500 members, thirty-five state and local committees have been organized, the necessary expenses have exceeded $60,000, and the printed matter issued has increased from a few leaflets to over 6,000,000 pages.

This committee considers that its greatest work lies ahead; abolition of fourteen-year age limit exemptions for poor children, closing the street trades to boys under fourteen and girls under eighteen; a sixteen year limit for dangerous occupations, and an eighteen year limit for extra hazardous occupations; to twenty-one year limit for boys called on to face the moral dangers of night messenger service; higher standards for proof of the requirements under child labor laws; regulation of hours of work for all minors and medical inspection for them (services rendered by no state in the union at present); broader public discussion of the need for a general sixteen year age limit; the education of children excluded from school to meet



the demands of an industrial age—such are some of the things the committee has set itself to work out.

The report closes with an appeal that by the anniversary day the members shall put the committee on a working basis of 100 guarantors, 1000 sustaining members, and 10,000 associate members.

BOSTON'S TUBERCULOSIS DEATH-RATE DECREASING RAPIDLY.

THE death-rate from tuberculosis in Boston has very rapidly decreased since 1882. This is graphically shown by a chart which appears in the tenth annual report of the Boston Association for the Relief and Control of Tuberculosis. This chart discloses the fact that from 1850 to 1882, 32 years, the death-rate from tuberculosis decreased only from 47⅛ to 42, or 5½ points per 10,000 inhabitants. The following 31 years, 1882 to 1913, the death-rate from tuberculosis decreased very rapidly, from 42 to 15, or 27 points. This rapid decrease in the second period is partly accounted for by the fact that in 1882 Dr. Robert Koch, discovered the tuberculosis germ. Before this time the cause of the disease was unknown, but as soon as discovered it was possible to take proper steps to suppress it by the establishment of hospitals and through vigorous educational campaigns. The organization of the Boston Association for the Relief and Control of Tuberculosis in 1903 and the establishment of the Boston Consumptives' Hospital Department in 1906 further assisted in reducing the death-rate.

The report further tells of the effort of the association to induce the city council to favor the appropriation of $125,000 for additional accommodations at the consumptives' hospital, recommended by the mayor and the consumptives' hospital department. This appropriation has since been passed. Other matters the association is interested in are the further extension of open-air schoolrooms throughout the city, the more general use of the night clinic at the consumptives' dispensary on Burroughs Place for those at work through the day who would like to be examined. Several legislative bills affecting tuberculosis and health, as well as the hearings conducted by the recess committee on tuberculosis, received considerable attention from

BOSTON TUBERCULOSIS CURVE.
Broken line indicates the number of deaths per 10,000 of population from Pulmonary Tuberculosis (Consumption).
Dotted line indicates the rate of decrease since 1882 continuing into the future.

the association. Experiments in domestic science and following up patients discharged from sanatoria and hospitals were carried on during the year.

The educational work was conducted by means of an exhibit, a part of a large health exhibit sent to different cities in the state under the auspices of the State Board of Health; the distribution of 171,000 pieces of literature to school children, night schools and at motion picture theatres; and by 352 illustrated lectures, 323 of which were given in 36 motion picture theatres of the city. These lectures were given to a total of about 148,500 persons. At Prendergast Camp a total of 61 patients were cared for during the year.

The expense of the association for the year amounted to $16,661.48. The expenses for the coming year may be greater, as the association has consented to finance, at least for the present, the Massachusetts Anti-Tuberculosis League, a state society the association took an active part in organizing this month. It is hoped that this league of the 35 societies in the state, fighting tuberculosis, will further assist in reducing the death-rate from this preventable disease.

THE DANGERS THAT ATTEND THE USE OF FUNCTIONAL TESTS, ALONE, IN MENTAL EFFICIENCY.

EVEN now that the newer psychology has opened a broad and promising therapeutic field, some physicians and many laymen are still attempting to account for, and perhaps correct, delinquency in offenders by determining their intellectual limitations (and afterward instructing) by cock sure tests, losing sight oftentimes of the fact that when the long hidden, and now subconscious, traumata of earlier life are unearthed and dispelled, the tendency toward crime may disappear, and more than this, the intellectual ability itself frequently improves and grows to a point that no one considered possible. The latter point has been demonstrated recently by Sprague and others of the Public Health Service in their work at Ellis Island. It is not to be wondered at then that women incarcerated for social sins, on whom a Binet test has been done with the result that they have been called "seven years old mentally." do test out this way, and that they return almost immediately to the old life from whence they came, especially when no attempt at analysis has been made.

It must be evident to all then that in any work with defectives some attempt should be made to get acquainted with the individual himself, and to learn the stimuli and complexes that go to make him exactly what he is, and further than this, to know how and why he differs from those who have apparently been exposed to a similar set of circumstances during the developmental period of their own lives. To express this more definitely, find out what experiences he had that the others may not have had, and which one or ones had the strongest effect on him and which relate to the intricacies of the present trouble.

With these suggestions in view it must be apparent that the study of defectives is an infinitely complex problem, and not one to be delegated to workers with mechanical tests, who have no knowledge of modern psychiatry, although performance tests are instruments of immense value when they are in the hands of people who are qualified to use them intelligently.

Many of us, I believe, look upon deficiency in most cases as being due at least to tangible physical conditions with consequent organic or toxic processes, whereas it may be due in a given case to states existing purely and solely in the psyche, and these, being caused by impressional stimuli having a peculiar and intense affective value for that particular individual, may have been at the bottom of the whole trouble, and until the exact percept can be disclosed but little progress will be made toward a successful termination of the case.

Another danger is sometimes encountered in the shape of those more or less transient disorders that arise as a result of recent psychic shock, such as incidents of an unpleasant nature, during which the individual may be able to do but little that requires slightly complex mentation. This shock is to the conscious mind what the repressed one is to the subconscious mind, and the psychogenic excitements and depressions are to the former as the hysterias, psychasthenias, neurasthenias, and minor neuroses are to the latter.

The lesson to be learned, therefore, is that the final disposition of all defectives, delinquent and otherwise, should be made on the advice of psychiatrists as well as psychologists, or, if necessary, a combination of both in one.

MEDICAL NOTES.

Treatment of Tuberculosis by Induced Pneumothorax.—Dr. Martin F. Sloan has been engaged as expert for three months to introduce the treatment of pulmonary tuberculosis by induced pneumothorax at the United States Public Health Service Sanatorium at Fort Stanton, New Mexico. Dr. Sloan is a graduate of Johns Hopkins Medical School, 1908, and since graduation has been on the staff of that institution as assistant in medicine. He is also on the staff of the Phipps Tuberculosis Dispensary, from which clinic he selects most of the patients for Eudowood Sanatorium (Hospital for the Consumptives of Maryland, Towson, Md.), of which institution he has been superintendent for the last four years. Eudowood will be remembered as the first institution in this country to establish a farm colony for convalescents and introduce graduated exercise as a therapeutic measure. Induced pneumothorax was introduced at Eudowood by Dr. Sloan in 1911 with an apparatus of his own, which is a modification of Saughman's. The Public Health Service Sanatorium at Fort Stanton offers an admirable field for the employment of induced pneumothorax because of the large number of far advanced cases and the opportunity which the government affords to retain under treatment beneficiaries who are disabled by their disease for a long period of time. Of the 200 patients under treatment, all adult males, thirty have been selected as suitable cases for treatment by this method. Dr. Sloan's engagement with the Public Health Service terminates March 1, when he will rejoin his sanatorium at Towson, Md.

Smallpox in Texas.—Report from El Paso, Tex., on Jan. 23 states that several cases of smallpox have been recently discovered among Mexican refugees from Ojiuja. The patients have been isolated, and all sightseers excluded.

State Hospital for Pellagra.—It was announced on Jan. 28 that a state hospital for the treatment and study of pellagra is to be established at Columbia, S. C.

Gift to Washington University Medical School.—The General Education Board has recently announced a gift of $750,000 to the medical school of Washington University, St. Louis.

Virginia Central State Hospital.—The recently published forty-third annual report of the Central State Hospital at Petersburg, Va., records the work of that institution for the fiscal year ended Sept. 30, 1913. During this period 990 male and 997 female patients were inmates of the hospital. Twelve of these had pellagra, of whom ten died. All the colored insane of Virginia are maintained in this institution, there being none in any almshouse, jail, or other local establishment.

American Society for the Control of Cancer.—The American Society for the Control of Cancer in coöperation with the Twentieth Century Club and the Pittsburgh Academy of Medicine held a public educational meeting on cancer, in the Soldiers' Memorial Hall, Pittsburgh, on Tuesday evening of this week, Feb. 3.

Invitations were sent to the most representative and influential people in Pittsburgh and vicinity, including members of women's clubs, men's clubs, bankers, manufacturers, attorneys, ministers, teachers, physicians, and others.

Hon. James R. Macfarlane presided, and Mr. Frederick L. Hoffman, the statistician of the Prudential Life Insurance Company, made the opening address. The chairman of the Committee on Organization of the American Society for the Control of Cancer described the purpose and plans of that Association, which has recently been formed as a national agency to disseminate knowledge concerning the symptoms, diagnosis, treatment and prevention of cancer; to investigate the conditions under which cancer is found and to compile statistics in regard thereto.

BOSTON AND NEW ENGLAND.

In Memory of Dr. Fifield.—Resulting from the International Medical Congress which met in London last summer, the gift of a clock for the Commons room at the Royal College of Surgeons has been made in memory of the late Dr. William C. B. Fifield of Dorchester, for many years on the staff of the Boston City Hospital. Dr. Fifield was an honored graduate of the Royal College and served several years in the London hospitals before beginning practice in Dorchester.

A Centenarian.—Mrs. Tahis Langervin, who died on Jan. 27, at Somerville, Mass., is said to have been born in 1808 in Canada.

A MEDICAL NONOGENARIAN.—In the issue of the JOURNAL for June 19, 1913 Vol. clxviii, p. 930) we commented editorially on "a remarkable group of nonogenarians," comprising the four survivors of the Harvard College class of 1838. Since that time, two of these venerable men have died. Dr. James Lloyd Wellington, of Swansea, Mass., therefore now becomes the oldest living graduate of Harvard College, as well as of the Harvard Medical School, the senior Fellow of the Massachusetts Medical Society, and the oldest physician in the United States. Dr. Wellington, who continues in his habitual good health, celebrated on Jan. 27 his ninety-sixth birthday anniversary.

SOCIAL SERVICE AT THE MASSACHUSETTS GENERAL HOSPITAL.—The recently published eighth annual report of the social service department of the Massachusetts General Hospital records the many and varied activities of that body for the calendar year 1913. It is of great interest to those concerned in this form of work.

WILMINGTON WOMEN'S CLUB.—On Monday of last week, Jan. 26, the Wilmington Women's Club held a meeting at the North Reading Tuberculosis Sanatorium. Dr. Carl McCorrison, superintendent of the sanatorium, in an address to the meeting, advocated strongly the establishment of local community hospitals for advanced tuberculosis in all adjoining municipalities having an aggregate population of 10,000 or more. Dr. Edwin N. Kent, president of the Dental Hygiene Council of Massachusetts, spoke on "The Care of the Human Mouth," and Mrs. Eva G. Ripley, of Wakefield, Mass., described the establishment of the District Nursing Association in that town.

WORK OF CHILDREN'S HOSPITAL.—The forty-fifth annual report of the board of managers of the Children's Hospital was submitted at the annual meeting of the corporation, held in Boston on Jan 28. During the past year 1815 patients were treated in the wards, 27,153 in the out-patient department, and 3075 in the social service department. The hospital will soon move to its new buildings on Longwood Avenue.

MASSACHUSETTS HOMEOPATHIC HOSPITAL.—The annual meeting of the corporation of the Massachusetts Homeopathic Hospital was held in Boston on Jan. 27. The report of the trustees emphasized the need of the hospital for a new maternity building and children's ward. During the past year 22,452 patients were treated at the hospital, of whom 6508 were ward cases.

NEW LEPER INFIRMARY.—Plans and specifications have already been drawn by the Massachusetts State Board of Charity for a new leper infirmary to be built on Penikese Island at an estimated cost of $40,000.

"The proposed infirmary will be a one-story structure either of concrete or tile construction, with a wing on either end with accommodations for bed patients afflicted with pneumonia or consumption, which follow closely upon the latent period of leprosy. Two sections of the infirmary will be devoted to a scientific observation of the disease. One will be equipped with an x-ray and other modern apparatus. In the other section of the dispensary will be a consulting room, in which will be preserved the records of every individual case."

INSURANCE LIABILITY FOR OCCUPATION INJURIES.—In a recent case, in which a workman lost the sight of both eyes from optic neuritis, due to inhaling fumes while tending a gas-producing furnace, the Massachusetts Industrial Accident Board awarded the plaintiff $3000 for total disability and $952 additional compensation. The insurance company against which this award was made appealed to the supreme court under the contention that the word "injury" in the statute denotes only an accident caused by some sort of blow. The decision of the court in this test case is of importance as a precedent in determining whether any industrial disease may be construed as a personal injury within the meaning of the law.

HOSPITAL BEQUESTS.—The will of the late Jesse F. Frisbie, of Newton, Mass., who died on Dec. 17, 1913, was recently filed at the Middlesex registry of probate. It creates a trust fund for the establishment and maintenance at Rochester, N. H., of a new hospital, to be known as the Frisbie Memorial Hospital.

The will of the late Mrs. Charles M. Day, of Worcester, Mass., which was filed for probate on Jan. 28, contains a bequest of $10,000 to constitute a trust fund, to be known as the Bancroft-Day Fund, for the benefit of the Milford (Mass.) Hospital.

The will of the late John Ware Willard, of Brookline, Mass., who died on Jan. 19, was filed

recently in the Norfolk county probate registry at Dedham, Mass. It bequeaths to the New England Hospital for Women and Children, the Children's Hospital, and the Boston Floating Hospital each one-seventh of all or any property which may be inherited from the testator's father. To the Children's Hospital, the Boston Floating Hospital, and the Boston Lying-in Hospital, it bequeaths each one-fourth of any and all property which may be inherited under the will of the testator's mother.

The will of the late Benjamin Leeds, of Roxbury, Mass., which was filed for probate on Jan. 27, contains a bequest of $50,000 to the Massachusetts Homeopathic Hospital.

The will of the late Morrill Wyman, of Cambridge, Mass., which was filed on Jan. 29, in the East Cambridge probate court, contains bequests of one-fourth of the residuary estate to the Cambridge Hospital and one-half to Harvard College to establish the Morrill Wyman Medical Research Fund in the Medical School.

NEW YORK.

An Appeal for Radium.—The New York Skin and Cancer Hospital has issued a formal appeal for the use of 500 milligrams of radium (which at present prices would be worth $50,000). In this appeal it is stated that the radium could either be given outright or loaned for a period of five years. Since one-half of the institution is devoted exclusively to the treatment of cancer, its authorities feel that it should have an opportunity to make an exhaustive study of the value of radium in such treatment. No less than 500 milligrams is required, since, in the opinion of experts, less than this amount would not afford a fair test of the usefulness of the agent for this purpose.

Donations to Mt. Sinai Hospital.—At the annual meeting of the managers of the Mount Sinai Hospital, held on January 25, donations of over $325,000 were reported. This amount includes the Benjamin Altman legacy of $100,000, a $100,000 legacy from Mrs. L. W. Neustader, and a gift of $125,000 from Joseph and Sophie Sachs, in memory of their parents, to endow two neurological wards of fifteen beds each. The total expenditures during the year were $469,892, and the income from all sources, $421,384, and the amount of the deficit was borrowed from the permanent fund. A silver service was presented to Dr. A. G. Gerster, senior attending surgeon, who retired from the hospital staff on Jan. 1, after a service of 39 years, and a silver Greek vase to Dr. Julius Rudisch, who retired to become consulting physician, after a service of 34 years on the active staff.

Appointment of Dr. Linsley R. Williams.—Commissioner Biggs has appointed Dr. Linsley R. Williams of New York deputy commissioner of the State Department of Health.

Venereal Diseases.—The city authorities having failed to make any provision for carrying on the work of the Health Department's division of venereal diseases during 1914, the Bureau of Social Hygiene has, as last year, come to the assistance of the department and has pledged a fund sufficient to maintain the positions of a medical adviser, one bacteriologist, six laboratory assistants, one stenographer, and three helpers. During 1913, 18,750 blood specimens were tested for syphilis, and 3,526 for gonorrhea. One orphan asylum now has Wassermann tests made on every child before it is admitted to the institution. In view of the fact that many physicians do not seem as yet to appreciate the attitude of the Health Department towards venereal disease, and that some persist in the belief that cases are being treated in the diagnostic clinics, a portion of a letter recently addressed to all physicians in the city has been reproduced in the *Weekly Bulletin* of the department. In this it is stated: "In order to extend the usefulness of these clinics in combating the spread of venereal diseases, a specially trained physician has been appointed to act as 'medical adviser' to the patients attending. Under no circumstances will he treat cases. His duties consist in advising patients as to the nature of their disease, the necessity of proper medical treatment, the dangers of self-treatment, and the importance of obeying the directions of their physicians."

A Centenarian.—Dennis Redmond of the Borough of the Bronx, New York City, died on January 21, after having just reached the age of 100 years. He was born in Dublin, Ireland, on Jan. 1, 1814, and came to this country in 1847. Until the age of 92 he had been in the employ of a well-known men's clothing firm in New York.

QUARANTINE FOR DIPHTHERIA ON THE "ARKANSAS."—Eight hundred officers and men were quarantined on Jan. 26, aboard the United States battleship *Arkansas*, recently arrived at Brooklyn from a Mediterranean cruise with a case of diphtheria.

LEGALITY OF COMPULSORY VACCINATION.—On Jan. 23, the appellate division of the supreme court handed down a decision affirming the recent conviction of a citizen for violation of the compulsory education law in refusing to have his son vaccinated. This decision is of importance as a precedent in declaring the legality of compulsory vaccination.

SMALLPOX AT NIAGARA FALLS.—Report from Niagara Falls on Jan. 29 states that during the three weeks then ended 133 cases of smallpox were notified in that city.

11. VERBRYCKE, J. R. *The Diagnosis of Gastric Ulcer.*

1. Libman reports an analysis of the clinical features of 21 cases of subacute bacterial endocarditis that spontaneously became bacteria-free. In 17 of the 18 cases that had died at the time of publication autopsies were performed, proving that the condition under discussion was present. The duration of the disease may be as long as two and a half years before death, and a few cases appear in literature that are reported to have survived. In most cases the early symptoms were cardiac in nature, but in some, uremia was rather suggested. Fever was less prominent than in the bacterial cases. Evidence of valvular lesions was present in all, but no new lesions are believed to have developed in the bacteria-free stage. Anemia was present in all, and in many cases was extreme. The spleen was palpable in all but four, and in some cases was enormously enlarged. Sweats and loss of weight were less prominent than in the bacterial cases. Embolism was as common as in the bacterial cases. Progressive brown pigmentation of the face was a striking symptom in nine cases and was seen to a marked degree only in the bacteria-free cases. The cases as a whole are separated into five groups according to their most conspicuous features: Marked progressive anemia, brown pigmentation of the face, marked evidence of renal disease, marked enlargement of the spleen, or embolic symptoms.

2. Foster reports the following results with the Noguchi luetin reaction: Of 13 cases of secondary treated syphilis, 77% were positive. Of 5 cases with tertiary lesions 80% were positive. Of 52 cases of syphilis in the stage of latency or cure, 88% reacted. Of 5 individuals presumably free from syphilis one reacted—a man in whom infection seemed highly improbable, but whose maternal grandmother was believed to have had tabes. It is concluded that the luetin test is of value to supplement the rôle of the Wassermann reaction, the latter being of greatest value in the earlier stages and the former in the tertiary and latent stages. Its prognostic value in determining whether the infection has been eradicated is emphasized.

3. De Costa's article is a reiteration of his belief in the value of light percussion over the thoracic vertebral spines in the diagnosis by the presence of dullness of enlargement of tracheo-bronchial glands or other mediastinal tumors.

4. Smith, Lynch and Rivas publish evidence that bed-bugs may take up the lepra bacilli with blood; that within the bugs for a time the bacilli increase in size and apparently in numbers, but eventually disappear; that the bacilli are found in the glands as well as in the alimentary canal of the bugs; that bed-bugs acquire lepra bacilli from leprous human subjects; and that they may transmit the bacilli to the skin of an animal bitten. The authors conclude, however, that if bed-bugs really do transmit the disease they are only one of a number of possible conveyers.

6. Thomas's article is one too comprehensive for profitable review, being rather an enumeration than a description of the many procedures now applied to the diagnosis and treatment of the male genito-urinary apparatus in all its divisions. Its perusal, however, brings strikingly to mind to what an extent bacteriology, serology, cystoscopy, radiography and chemistry have advanced and complicated the subject.

7. Warren reports that fluoroscopic study of a case of bronchial asthma showed that the pulmonary distention continued for several weeks after the cessation of a prolonged attack, the heart maintaining a vertical position. During the attack the diaphragm moved but slightly, and in movements in reverse of the normal.

10. Stetten and Rosenbloom report upon results of metabolism experiments in a marked case of hypopituitarism. Of chief note was the finding of high and abnormal percentages of the neutral sulphur and of the undetermined nitrogen in the urine. [F. W. P.]

1 and 2. The papers of Wilson and of Plummer are the result of studies of the large material of the Mayo Clinic. In a previous report, Wilson showed that among thyroids removed from toxic goiter cases pathologically the glands were divided between two distinct types. Clinical studies carried on with Plummer have now led to the conclusion that toxic goiter cases may be divided into two classes, the exophthalmic and the non-exophthalmic. It is now shown that of 1208 cases of toxic goiter, 79% had glands showing primary hypertrophy and hyperplasia, and practically without exception had the clinical features of true exophthalmic goiter. The remaining 21% of the cases had goitres showing either regenerations or adenomas, and none of these were grouped clinically as true exophthalmic goiter.

3. Blackford and Sanford report evidence that fresh extracts made from exophthalmic thyroids contain a powerful depressor substance, and that a powerful depressor substance likewise exists in the blood

serum of cases of exophthalmic goitre in direct proportion to the clinical acuteness and severity of the diseases. The sera of patients with non-hyperplastic thyroids, on the other hand, do not have a depressor action. After an active depressor dose of serum from a case of exophthalmic goiter the depressor action of the extract of an exophthalmic goitre is weakened or abolished, and the converse of this is also true.

4. Russell's article is a careful summary of the evidence upon which the efficacy of antityphoid vaccination is based. Those interested in the details of this subject will do well to consult this work.

6. Taylor reviews the etiology of brachial birth palsy, and protests that contrary to common teaching the prognosis under expectant treatment is exceedingly bad. It is, moreover, aggravated by the fact that the deformity, at first functional, later becomes fixed by secondary organic pathological changes. From his experience with 43 operated cases he is convinced that the prognosis is much improved in cases treated surgically. The operation consists of incision through the skin and fat at the base of the neck, suture of ruptured nerves, fixation for a period, and then careful passive and later active motion. The time of choice for operative interference is from two weeks to three months after birth.

7. Einhorn describes cases of pylorospasm and of stricture of the pylorus treated by instrumental dilation, according to his method previously published. This method is not supported as a substitute for surgery, but is advocated in functional cases and in cases where surgical interference cannot be applied.

8. Brill and Mandelbaum discuss at length the condition known as Gaucher's disease, of which but 14 proved cases are recorded in the literature. The disease occurs chiefly in childhood and often in more than one member of the same family. Its features are a progressive enlargement of the spleen and later of the liver, to an enormous size, with a brownish yellow discoloration of the skin of the face, neck and hands, and a yellowish thickening of the conjunctivae. It has a prolonged course, which does not materially disturb the health of the patient. The blood shows a definite leukopenia. The pathological feature is the presence in the spleen, liver, lymph-glands and bone marrow of distinctive large cells of unknown origin, to which the enlargement of the liver and spleen is due. [F. W. P.]

1. It is recognized that the symptom of pain in pleurisy may be referred to the abdomen, neck or to the shoulder joint. The abdominal pain is usually explained as being due to a sympathetic stimulation of those intercostal nerves whose roots originate in the same region as the nerves supplying the injured pleura. Less attention has been paid to pain referred to the shoulder joint. Gerhardt reports four cases of different types of pleurisy with such pain. It was so severe in two cases that the diagnosis of arthritis was made. He explains the symptom as being a reflex stimulation of those peripheral nerves whose fibres originate in the same spinal segments as the sensitive fibres of the phrenic nerve.

4. The methods in use for ridding patients of excessive fat are by dietetics, by physico-mechanical means, or by medicines. Bergioné's electrical instrument has received much attention lately, and Roemheld has conducted experiments to determine its value. His conclusions are that Bergioné has merely offered a passive means of muscular exercise to substitute active exercise during the time of the cure. The use of the machine alone produces no definite loss of weight, and it is only effective when a dietetic cure is undertaken at the same time. [R. F.]

4. The author's method of using fluorescein is to give one gram by mouth in the morning; to estimate roughly the time of appearance by having the patient void every few minutes; and then at the end of thirty hours have the patient void once an hour till the fluorescence no longer appears in the urine. The test is done entirely with the eye, as the only points to be observed are the time of appearance and the end-point of the excretion. The urine should be made alkaline. Normally the drug appears in from ten to twenty minutes and is all excreted in from thirty-five to forty hours. If the total excretion takes between forty and 50 hours the renal capacity is suspicious, over fifty hours the author considers pathological. This is only a rough test, but in a few cases it has run parallel to other functional tests—phthalein, and potassium iodide. About thirty cases were tested in all, and so far as described in this article fluorescein does not seem to be so useful as phenolphthalein.

5. Glaser reports the case of a boy of twelve with severe subacute nephritis, with edema, ascites and hydrothorax, in whom an extensive erysipelas of the trunk and thighs was followed by a complete clinical cure of the nephritis, the urine showing neither albumin or sediment. He has collected four other cases, from the literature, of chronic nephritis being apparently cured in the same way. He advances two theories to explain these cases—first, that the erysipelas gave rise in the body to fresh streptococcus antitoxins which influenced favorably renal lesions caused by streptococcus toxins; and, second, that favorable circulatory changes might have been brought about in the kidney by the intense hyperemia of the skin. [R. H. M.]

8. KOPPEL, M. *The Fluid Absorption of Organic Tissue with Different Hydrogen Ion Concentration.*

1. In this article Schott takes up the question of preservation of life by means of injection of nourishment directly into the circulation rather than by absorption through the alimentary tract. He has studied the effect of such injections from many points of view and reports his findings here. His work has been in good part experimental. He concludes that rabbits and dogs can be held in nitrogenous equilibrium by injection of egg yolk and salt solution up to the appearance of anaphylactic phenomena. This albumen will only in a small percentage be present in the urine as coagulable albumen. Most of it is burnt in the organism. The fat so introduced disappears from the circulation in about 1½ hours and is apparently used as nourishment. Carbohydrates introduced intravenously as dextrose appear to offer the means for burning albumen in the organism just as when introduced through the digestive tract. The anaphylactic appearances occur about on the fourth or fifth day with rabbits and at the fourteenth day with dogs.

2. Eisner has studied the effect of calcium salts upon the renal function in man. As a test for renal function he has studied iodide excretion. Milk sugar excretion, sodium chloride excretion, nitrogen excretion, phenolsulphonephthalin excretion and water excretion, as well as the excretion of calcium salts. He used calcium lactate as his calcium salt. In only one case in any of the functional tests was there any improvement after calcium. In others no improvement or a diminution of function. He feels that although calcium may not help renal function it may still be of some value in certain renal conditions, just as atophan aids the permeability of the kidney for uric acid. [C. F., JR.]

Miscellany.

RELATIVE SIZE OF AMERICAN UNIVERSITIES AND MEDICAL SCHOOLS IN 1912 AND 1913.

IN a recent issue of *Science* are tabulated the registration returns for Nov. 1, 1913, of thirty of the leading universities of the United States. Of these only three,—Harvard, Western Reserve, and Yale,—show a decrease in numbers from 1912. The order of size of the thirteen largest universities in 1912 was Columbia, California, Chicago, Harvard, Michigan, Cornell, Wisconsin, Minnesota, Pennsylvania, New York, Illinois, Northwestern, and Ohio. In 1913 these thirteen remain in the lead, but their order is changed as follows: Columbia, California, Chicago, Michigan, Pennsylvania, Wisconsin, Harvard, Cornell, New York, Illinois, Ohio, Minnesota, and Northwestern. In number of undergraduates, however, Harvard still stands first, and is followed by California and Michigan. Among the medical schools the order of size in 1913 is Illinois, New York, Tulane, Johns Hopkins, Michigan, Columbia, and Harvard.

FIRST NATIONAL CONFERENCE ON RACE BETTERMENT.

FOUR hundred men and women of prominence, comprising the first representative group of scientific experts ever gathered in America for that purpose, met in Battle Creek, Mich., Jan. 8-12 to assemble evidence of race deterioration and to consider methods of checking the downward trend of mankind. The meeting was known as the First National Conference on Race Betterment. Through the coöperation of the press, the objects and aims of the Conference

have been very widely disseminated and a resultant influence for better race ideals is anticipated.

Already the effect of the Conference is apparent in Battle Creek, where popular interest in mental and physical efficiency was awakened by a series of public school tests which showed an alarming percentage of defective children in all grades.

The conference had its inception in the efforts of four men, particularly interested in race betterment—Rev. Newell Dwight Hillis, pastor of Plymouth Church, Brooklyn, N. Y.; Dr. J. H. Kellogg, of the Battle Creek Sanitarium; Sir Horace Plunkett, former minister of agriculture for Ireland; and Prof. Irving Fisher of Yale University. At the invitation of a central committee, chosen largely by these men, fifty men and women of national prominence in the fields of science and education, consented to share in the program. Their addresses, together with open discussion of many of the points considered, constituted a very widespread study of all phases of evident race degeneracy and the advocacy of many ideas of reform. Some of the suggested methods of improvement are frequent medical examination of the well, outdoor life, temperance in diet, biologic habits of living, open air schools and playgrounds, the encouragement of rural life, the segregation or sterilization of defectives, the encouragement of eugenic marriages by requiring medical certificates before granting license and the establishing of a eugenics registry for the development of a race of human thoroughbreds.

Correspondence.

INFECTION IN TUBERCULOSIS.

Mr. Editor: My attention has been called from several sources to an article in the *Christian Science Monitor* of Jan. 24, 1914, which purports to present my ideas as to infection in tuberculosis. The article mentioned quotes only a part of a paragraph relating to the subject and which was quoted in an editorial by the *Journal of the American Medical Association* in a recent issue. (Jan. 3, 1914.)

The part which they quoted was so used as to give the impression that I did not believe tuberculosis was infectious. As a matter of fact it was intended to explain the well-known belief at present that childhood is the time of infection, and that more protection ought to be given for children and more hygiene for adults. A reference to this editorial would make this entirely clear.

The original paper related to the fact that a certain degree of immunity is acquired by adults by small infections occurring in early life which gave them more or less immunity against infection later. It was in no way stated that tuberculosis was not infectious nor should I be misrepresented in this way. Not only do I believe tuberculosis to be infectious,—and especially so for persons who have not been protected by mild infections in childhood,—but chiefly from the open case of tuberculosis is the danger very great in the home where small children come in contact with the patient. On no account do I oppose the movement for the segregation of the open tuberculous, but my plea was for more reasonableness in the attitude of adults as to their own danger. I am strongly in favor of all the measures which are aimed to protect the public and to care for all classes of tuberculous patients. It is extremely wrong and I am greatly chagrined that my statements should be used to represent any other idea. I am

Respectfully yours,

EDWARD R. BALDWIN, M.D.

MEDICAL CORPS, U. S. NAVY.

The following changes have been made in the Medical Corps, U. S. Navy, for the week ending January 24, 1913:

January 16, P. A. Surgeon B. H. Dorsey, detached: Camp Elliott, Canal Zone, to *Connecticut*.

SOCIETY NOTICES.

The next meeting will be held on Tuesday evening, February 10, in the amphitheatre of the Peter Bent Brigham Hospital at 8.15 o'clock. Program:

"Exhibition of Cases," Dr. A. Luger. "Spastic Conditions of the Stomach," Thomas Ordway, S. F. Hammett, Wm. J. Kerr. "The Effects of the Surface Applications of Radium over the Spleen in a Case of Chronic Lymphatic Leukemia," Dr. William Duane.

Remarks on the Surgical Properties of Radium and Its Derivatives.

THOMAS ORDWAY, *Secretary and Treasurer*,
Harvard Medical School.

HOSPITAL MEETING: MASSACHUSETTS GENERAL HOSPITAL.

The next hospital meeting will be held at 8.15 p. m. on Feb. 13, 1914 in the lower amphitheatre of the Out-Patient Department. The subjects are to be as follows:

1. "Causes of Scoliosis," by Dr. Z. B. Adams.
2. "Back Pain and Its Diagnosis," by Dr. Harry Platt.
3. "X-ray Diagnosis of Lesions of the Lumbar Spine and Sacro-iliac Joint," by Dr. C. Hermann Bucholz.
4. "Use of Plaster Backs in Post-operative Backache," by Dr. John McCartin.

APPOINTMENTS.

DR. EARL H. MACMICHAEL has recently been elected city physician and DR. WALTER W. KINGSBURY a member of the board of health of Malden, Mass.

DR. HARRY E. SEARS of Beverly, Mass., has been comfirmed as Associate Medical Examiner of Essex County.

RECENT DEATHS.

DR. JAMES HARVIE DEW of New York died from cerebral apoplexy on January 26, at the age of 70 years. He was a native of Newtown, Va., and served for a time in the Confederate Army. He was graduated from the medical department of the University of Virginia in 1867, and afterwards was an interne at the Charity (now City) Hospital, New York. Dr. Dew won for himself a very large clientèle, especially among the southern families living in New York. He was one of the most genial of men, and his death will be sincerely mourned by a host of patients and friends.

BOOKS AND PAMPHLETS RECEIVED.

Leitfaden der Säuglingskrankheiten für Studierende und Ärzte von Dr. Walter Birk. Bonn, 1914. A. Marcus & E. Webers Verlag.

Original Articles.

OBSERVATIONS ON PEPTIC ULCERS.*

BY CHRISTOPHER GRAHAM, M.D., ROCHESTER, MINN.

INTRODUCTION.

IN this paper are presented notes on all cases of duodenal and gastric ulcers operated on in the Mayo Clinic during the years 1906 to 1911, inclusive; and our observations on diagnosis and statistics are based upon a study of the clinical records and operative findings.

It is often difficult, and it may be quite impossible, to differentiate, clinically, gastric and duodenal ulcers, from other lesions causing gastric symptoms. It is often quite as difficult and it may also be impossible to locate the lesion in the stomach or duodenum if we have only the clinical picture to point the way. The symptoms of duodenal and gastric lesions may give exactly the same clinical picture, and for this reason we cannot at all times be definite when we attempt the localization of the ulcer. The radiogram gives the clinician aid in these cases, and at times not only locates the lesion, but makes positive the diagnosis in some cases with irregular histories. However, the clinical history is still our greatest factor in the differentiation of lesions causing gastric disturbance, and we should consider it carefully in all its phases.

The various types of ulcers as observed in our clinic are almost wholly chronic in character, the acuteness or subacuteness depending more or less on acute exacerbations, *i.e.* inflammation, infiltration, edema or perforation.

In discussing the diagnostic features of duodenal and gastric ulcers we should consider, first, the periodicity of the attacks; second, the chronic course; third, the significant symptoms that appear during the period of attack; and, fourth, the more or less ready control of symptoms, *e.g.* pain.

(1) *Periodicity of attacks* is almost constant in the duodenal and pyloric types of ulcers in which complications are not far advanced. When a patient presents himself with a history of attacks of gastric disturbance occurring day after day for several days or weeks, followed by remissions, or intermissions of weeks or months of perfect health, one strongly suspects an ulcer. The onset of attacks often comes without apparent cause. However, close application to hard work, worry, anemia, exposure and infection may be important contributing factors. During attacks the patient complains of pain, gas, sour regurgitations and vomiting, coming regularly after meals, and more or less controlled by food. This identical picture is presented each day during the period of attack. Intermissions occur of complete relief for days, or, if the ulcer be situated high up, a remission may be experienced, if not a complete period of ease. These attacks and intermissions alternate for years with "spring and fall" influence often noted. They increase in frequency, number and severity until the patient seeks relief in treatment. Such a history of periodicity is often quite enough in itself to warrant a probable diagnosis of ulcer.

(2) *Chronicity.* The patient rarely fails to emphasize the fact that these distressing symptoms have been coming and going for many years until finally he is forced to seek relief. The symptoms have remained the same in character, but have increased in length of period and intensity, until some complication has arisen to disturb the characteristic course. In general, the cases observed in our clinic have covered a course of many years, few less than one, the greater number falling between five and twenty years, the average being from eleven to twelve years. When we consider the average long series of years the symptoms have existed, with the distress always increasing and, as years go by, with invalidism increasing and often becoming quite complete, it seems strange, not that so many patients have been urged to seek relief in surgery, but rather why surgical measures were not urged earlier, at least on the appearance of symptoms indicating that the medical borderline had been passed. In our series, this history of prolonged attack with intermission or remission covering years was clear in 85% of the cases, and is a factor to be taken into serious consideration.

(3) *Pain.* During the period of attack, pain is the most constant symptom (pain or distress, 95%) and it is characteristic in its manifestations. The location of the pain, its type and its area of radiation are of secondary diagnostic significance: (*a*) because most pain is described as epigastric regardless of the location of the lesion causing the gastric syndrome; (*b*) because the pain complained of varies from mild distress, burning, griping or colic to a severe type requiring opiates for relief; and (*c*) because radiation is not common in uncomplicated ulcers and because if a clear-cut radiating pain to the back occurs, as in some posterior perforating ulcers, or if the radiation is to the lower abdomen, cholecystitis or appendicitis may be inferred. Thus our diagnosis may be clouded rather than cleared by the radiation.

(4) *Time and Control of Pain.* It is the time of pain and the control of pain that are characteristic and diagnostic. The time of its appearance, the time and manner of disappearance, and its control by food, alkalies, position and rest (vacation) are quite conclusive evidences for a correct diagnosis. Pain appears after meals, or in clear-cut duodenal types two hours before meals. It usually comes one-half to four hours after eating, depending in a measure on the location of the lesions. The nearer to the gastric outlet the

* Read before the Kalamazoo Acad. of Med., Dec. 9, 1913.

longer the period of food-ease is the rule. A burning, gnawing, painful feeling begins sooner or later after meals, following a definite type in each case, increasing in severity and continuing until the stomach empties, and pain ceases before the time for the next meal or continues up to meal time. The early cessation of pain is noticed most often in the histories of ulcers occurring above the pylorus. The pain, beginning later (two to four hours) as in purely duodenal types, may continue until vomiting, irrigation, alkalies, or the next meal brings relief. Food relieves pain, gas and acidity in a large percentage of cases (76%). This relief lessens as the pathologic lesion extends, and in the late stages little or no ease comes from food. Indeed, when complications, such as perforations, adhesions, and obstruction, are far advanced, food usually gives immediate pain, and only forced vomiting and irrigation afford relief. Alkalies are less efficient at this time than in the earlier stage.

The pain and accompanying symptoms then appear in definite periods of attack. They come daily, often two or three times a day at a definite time after ingestion of food during the entire period of attack. The onset of symptoms varies from one-half to four hours after meals, and they are oftener premeal than after-meal. The pain is epigastric, seldom radiating to other areas, and except in the later stages is relieved in part or fully by food, drink, alkalies, vomiting or irrigation.

What, then, are the typical diagnostic symptoms of peptic ulcer? (1) The period of attacks and perfect intermission or marked remission of attacks; (2) the almost exact similarity of symptoms occurring for days during the period; (3) the marked relation of symptoms to food intake (one-half to four hours); (4) the control of symptoms by food, alkalies, lavage, posture and rest.

The types of cases in which it is particularly difficult to reach a correct diagnosis, or in which it is quite impossible to differentiate from other lesions causing gastric symptoms may be divided into four groups:

Group 1. This group comprises those patients with ulcers who give the classic symptoms of gall-stones, and in whom no other gastric symptom can be elicited. In this group there may be perforations, or, the pain may be due to acidity and accompanying spasm. The lesions are usually chronic and may be located at any point in the stomach or duodenum. At operation, perforation has been found in about one-third of this group (35% duodenal, 29% gastric) and in some of these, at least, the pain has not been more intense than in those not found perforated at operation. Severe pain may be complained of and no perforation be evident. Patients with this symptom-complex constitute about 5% of all the cases. In them the diagnosis of gall stones is the only logical one to be made. Careful clinical research and radiography should lessen our errors.

Group 2. In this group may be found patients in whom the ulcer must have been latent for weeks or months, and whose first manifest symptoms were those of chronic ulcer with complications (hemorrhage, perforation, etc.). The symptom-complex in these cases is irregular and quite excludes the pathognomonic picture of ulcer.

Group 3. In these cases the present chronic symptoms are very severe. The early symptoms were so mild that they may have been quite forgotten or overlooked by the patient. Many such patients will not allude to the early trouble unless carefully questioned, because nothing is of so much importance to them as the present, or recent years of distressing pain.

Group 4. In the fourth group are those patients whose symptoms are of a more or less malignant type—marked loss of flesh and strength, pain or distress quite continuous, gas rather annoying and vomiting of large amounts at irregular periods. The vomitus consists of food, fairly macerated, perhaps dark, coffee-ground color and the liquid quantity quite in excess of fluid ingested. If to these symptoms is added the presence of tumor, we are inclined to err in diagnosis and consider cancer first. Three per cent. of all ulcers in this series were diagnosed cancer. Five per cent. had gross tumors, three per cent. more or less feel of ridge.

The cases in these groups may be variously diagnosed as acute or chronic gall-stone disease, gastric ulcer, chronic appendicitis, tuberculous intestinal involvement or cancer, in accordance with the variation of the symptoms. Here, too, by a more careful attention to clinical histories and more frequent use of the Roentgen ray we should materially lessen our errors.

In diagnosing atypical cases, one should take into consideration the variations in symptoms. The following groups suggest themselves:—(1) Those cases of a clear-cut gall-stone type. (2) Those which were chronic and complicated since the first symptoms appeared, *i.e.*, chronic ulcers long latent. (3) Those in which the ulcer is high on the gastric wall and tends to continuous symptoms without food ease; and (4) Cardiac ulcer usually with but slight symptoms until obstruction appears. However, the general picture is so clear that 80% of all ulcers may be followed closely enough to establish an accurate clinical diagnosis, and a probable diagnosis may be consistently made in the remainder.

Ulcers of the duodenum and pyloric area without complications are usually so clear-cut in their symptomatology that they may be diagnosed with little trouble. Ulcers located higher up may simulate the duodenal type closely and be thus diagnosed, or they may vary in symptomatology just enough to be atypical, yet be clearly gastric.

Other things being equal, the histories of uncomplicated types of duodenal and pyloric ulcers are clean-cut throughout the entire symp-

tomatology. The longer the period between food intake and onset of symptoms, the lower the ulcer as a rule. The more prompt the food ease and cessation of symptoms, the lower the ulcer. In ulcer of the stomach proper, the attacks are not so clear-cut as in duodenal and pyloric types, nor are the day-by-day symptoms so clearly defined. In those well above the pylorus the symptoms are apt to be continuous for longer periods, or remissions rather than free intervals are apt to be noted. These symptoms are not so often eased by food, or small amounts of food may give relief, while increased food may give distress. More care in diet is necessary. Soda relieves when food does not. Pain begins earlier as a rule, oftentimes disappearing before the next meal, and thus the food relief feature is minimized, but pain ½ to 1 hour after food, is quite the rule, and is of great diagnostic significance.

A gnawing sensation coming regularly when the stomach is empty, is almost "hunger pain." In such instances the effect of food may be translated as distress-producing, though it relieves the gnawing. Radiation of pain and the area of complaint are considerably more extensive in gastric than in duodenal types.

Vomiting in gastric ulcer is rather more common than in ulcers of the duodenum and pylorus unless complications, *e.g.*, obstruction, are present. Also vomitus containing food is more apt to come sooner, hence it is not in so advanced a stage of digestion. Blood is more frequent in the vomitus of cases of the gastric type.

In those conditions which oftenest cloud the diagnosis, such as chronic gall stones, chronic appendicitis, etc., we obtain our greatest diagnostic aid from the wide irregularity of symptoms during the period of attack. Yesterday's pain came before meals, today's pain after meals, tomorrow's pain an all-day "miserable feeling." Food-ease yesterday because fasting the previous day, today food pain wholly reflex; vomiting one day and gas another; yesterday well, today in the depths mentally. Nothing follows in sequence day by day, because the stomach behaves properly unless irritated by the distant lesion and this extrinsic lesion is irregular in its influence. The stomach then delivers what symptom it may when the irritation is great enough.

If attacks of "indigestion" occur, which are not quite clear-cut, if during the attack there is lack of regularity of symptom, if the pain be somewhat continuous, if remissions, even, are not marked, if together with the gastric symptoms of distress, gas, bloating, sour regurgitations or vomiting, continuing for a few days, to longer periods; and if each day the symptoms quite nearly repeat those of the day before; if some relation to food be observed; if the symptoms come on ½ to 1 hour or more after meals, if alkali or irrigation gives relief—if these conditions prevail, we may safely exclude from the diagnosis everything but peptic ulcer. Added to this, if we obtain a history of partial and fairly constant food relief, we may be quite sure of our diagnosis. In locating the ulcer, one may be aided by the field of radiation, as when it is high and well to left, or when there is perforation at any point. The patient's interpretation of pain and of the field of radiation is often perplexing. Localization by means of tender abdominal pressure-points is not wholly satisfactory, partly perhaps because of the varying positions of the stomach. The Roentgen-ray helps in many perplexing cases and promises even greater aid in the near future.

However, the greatest benefit to be derived from a diagnosis does not come from exact localization of the ulcer, but rather from the diagnosis of a lesion, and determining the patient's needs as to treatment, in the light of the available symptoms. Whether or not a patient be advised to undergo medical or surgical treatment often depends upon our viewpoint and is a theme for discussion by itself. Cases complicated with obstruction, hour-glass contraction, perforation and hemorrhage are conceded as being surgical. Patients suffering from oft-repeated or continuous attacks and whose usefulness or pleasure in life is greatly diminished thereby, certainly should be given the relief afforded by surgery, even though the above complications are not present.

STATISTICS.

The following statistics are based on the reports received from 600 cases of duodenal and gastric ulcer out of a total of 816. The shortest period since operation in these cases is now nearly two years.

Of all the patients with ulcer operated on during the years 1906-1911 inclusive, 76% were males and 24% were females. Of the males, 70% of all ulcers were duodenal or involved the duodenum. Of the females, 60% of all ulcers were duodenal or involved it.

Out of a total of 567 cases of duodenal ulcer operated on during a period of 6 years (1906 to 1911), information has been received concerning 438. The classified results of these data are as follows: 307 or 70% cured, 79 or 18% much improved, 40 or 9% fair, and 12 or 3% unimproved. A percentage therefore of 88 were cured or much improved. In 440 of the cases, the ulcer was confined to the duodenum. Of these 337 were heard from: 70% were cured, 16% much improved, 11% fair, and 3% not improved. In the remaining 127 cases, the ulcer extended to or involved the pylorus, and of these 72% were cured, 24% much improved, 3% fair, and 1% unimproved. That is, eighty-six per cent. of the former were cured or had made satisfactory improvement, whereas, in the latter group, in which the lesion was more extensive, 96% were cured or much improved. The results are summarized in the folowing table.

TABLE I.

ULCER

	Duodenum.	Duodenum. Involving Pylorus.	Total.
Number operated on	440	127	657
Number reporting	337	101	438
Cured	70%	72%	70%
Much improved	16%	24%	18%
Fair	11%	3%	10%
Not improved	3%	1%	2%
Cured and much improved	86%	96%	88%

There were 249 cases of gastric ulcer and reports were received from 162. These were grouped according to their situation: (1) 52 in or at the pylorus (pyloric ulcer), and (2) 197 in other parts of the stomach (principally the lesser curvature). Taken collectively, 95 or 59% of this series were cured, 35 or 22% were much improved, 21 or 13% fair improvement and 11 or 7% unimproved. Therefore, 80% were either cured or much improved, 93% were benefited and 7% not improved. Tables II. and III. show comparative results in this series.

TABLE II.

Cured	70%	58%	67%
Much improved	18%	22%	19%
Fair	9%	13%	10%
Not improved	3%	7%	4%
Cured and much improved	88%	80%	86%
Benefited	97%	93%	96%

Clinical observation goes to prove that the more advanced the obstruction at the pyloric end, other things being equal, the better is the result following gastrojejunostomy, and conversely, it is equally true that those cases with slight or no obstruction are to some degree less benefited by the operation. In the latter instance this result has been explained on the theory that the pylorus remains open and a portion of the food with its irritating, though perhaps normal acids, continues to pass by way of the natural channel coming in contact with the ulcer as before, thus giving a lessened opportunity for the ulcer to heal. This condition of free passage of gastric content by the natural route has been repeatedly verified by post-operative screen and Roentgen-plate study, yet many patients whose stomachs are thus functionating are, nevertheless, without symptoms. It is, however, because of this failure to relieve all patients that the surgeon has undertaken various procedures to overcome this difficulty, among which are excision or infolding of the ulcer, infolding the pyloric end of the stomach, ligation by means of silver wire or twine, and, more recently, the employment of a ligature of live tissue of fascia or omentum, none of which methods has been signally successful.

Pyloric obstruction to a variable degree occurred in 198 or 34% of the 576 cases of duodenal ulcer. Gastric analyses showed food remnants in varying amounts after 12 hours, in 100 cases or 50%. Reports were received from 163 patients. Nine had died since the operation. Ninety-four per cent. of the remainder were cured or greatly improved.

In 197 of the cases of gastric ulcer, obstruction was present in 78, or 39%. Food remnants were noted in 58, or 71%. Thirteen patients had died since operation. Ninety-two per cent. of the remainder were cured or greatly improved. The results in these two series (Table IV.) are encouraging in view of the fact that some complication, such as chronic or subacute perforation, regional peritonitis and adhesions, multiple ulcers or coincident disease in the gall bladder or appendix, or both, were frequently noted at the operation.

TABLE IV.

PYLORIC OBSTRUCTION.

ULCER

	Duodenum.	Stomach.
Number operated on	198	78
Number reported	163	52
Food remnants	25%	71%
Cured	71%	67%
Much improved	23%	25%
Not improved	3%	2%
Cured and improved	94%	92%
Fair	3%	6%
Complication	40%	43%
Other operations	18%	7%

The number of duodenal ulcers without evidence of obstruction either clinically or at operation was 275. The results were classified as follows:—Cured, 68 %; much improved, 17%; fair, 12%; not improved, 3%; cured and improved, 85%; total number benefited by the operation, 97%.

TABLE V.

DUODENAL ULCERS WITHOUT OBSTRUCTION.

Number reported	275
Cured	68%
Much improved	17%
Fair	12%
Cured and improved	85%
Not improved	3%
Benefited	97%

Of 162 gastric ulcers there were 110 without evidence of pyloric stenosis. The results were classified as: Cured, 51%; much improved, 23%; fair, 14%; not improved, 12%; cured and improved, 74%; total number benefited by the operation, 88%.

TABLE VI.

GASTRIC ULCER WITHOUT OBSTRUCTION.

Number reported	110
Cured	51%
Much improved	23%
Fair	14%
Not improved	12%
Cured and improved	74%
Benefited	88%

TABLE VII.

SUMMARY.

ULCER.

	Number.	Cured.	Much Improved.	Fair.	Cured and Improved.	Benefited.
Total duodenal	436	70%	18%	10%	88%	98%
Duod. (obstructed)	163	71%	23%	3%	94%	97%
Duod. (no obstr.)	275	68%	17%	12%	85%	97%
Total gastric	162	58%	22%	13%	80%	93%
Gastric (obstr.)	52	67%	25%	6%	92%	98%
Gastric (no obstr.)	110	51%	23%	14%	74%	88%

By a comparison of the results obtained (See Table VII.), it will be noted that the percentage of cured and improved cases of duodenal ulcer with obstruction was 94%, without obstruction, 85%, making a difference of 9%. The number of cured and improved cases of gastric ulcer with obstruction was 92% and without obstruction 74%; a difference of 18%. The comparatively good end results in these cases of duodenal ulcer without obstruction may be explained on the theory that: (1) The ulcer in healing contracts and causes partial or complete pyloric or duodenal stenosis. However, the end results in gastric ulcers without obstruction are so successful that the clinician need not delay his surgical diagnosis until obstruction or other serious complication endangers the patient. (2) In about 50% of the cases classified as obstructed, the degree of obstruction was only moderate, and from a practical standpoint, the end-results between these and the unobstructed cases should be very similar. (3) Undoubtedly the reflux of bile and pancreatic secretion from the duodenum into the stomach with its strong neutralizing action upon the hyperacid gastric contents favors healing of the ulcer and consequent remission of all symptoms. (Paterson.)

It may be that the improved drainage better defends the duodenum and pylorus, on account of their situation, from the irritating gastric content, or as a result of the operation, the acid irritation is lost to the duodenal and pyloric areas. Thus in this location healing is hastened. Ingested matter and acidity may still irritate the ulcer higher up (cardiac end).

TABLE VIII.

DUODENAL ULCER.

POST-OPERATIVE SYMPTOMS: DEGREE OF IMPROVEMENT.

Symptoms.	Before Operation.	After Operation.
Influence of food:		
Pain eased	76%	3%
Distress and pain	16%	17%
No effect or agrees	9%	80%
Vomiting	70%	13%
Gas	80%	18%
Hem.	19%	7%
Loss, weight	70%	10%
Gain, weight		68%
Constipated	58%	8%

In the series of duodenal ulcers, 106, or 19%, of patients gave a history of hemorrhage preceding operation. Thirty-one patients had hemorrhage of variable degree following the operation, but only 18 of these had hemorrhage prior to operation. Therefore there was hemorrhage in 13 cases following operation in which there was no history of pre-operative bleeding. In these the hemorrhage occurred some time after operation and was severe in only a small percentage. Out of a total of 108 patients, 94, or 88%, had a gastrojejunostomy performed, only 4% had excision or infolding of the ulcer in addition to gastrojejunostomy. Excision or pyloroplasty was done in 8 cases, or 8%. Three of the patients had post-operative hemorrhage in which excision or infolding had been done.

TABLE IX.

GASTRIC ULCER.

POST-OPERATIVE SYMPTOMS: DEGREE OF IMPROVEMENTS.

Symptoms.	Before Operation.	After Operation.
Influence of food:		
Pain eased	60%	1%
Distress and pain	30%	23%
No effect or agrees	11%	76%
Vomiting	71%	19%
Gas	81%	20%
Hem.	23%	6%
Loss weight	73%	12%
Gain weight		61%
Constipated	62%	15%

Forty-eight, or 23%, of patients with gastric ulcer had hemorrhage prior to operation. Eight patients, or 13%, had post-operative hemorrhage and of this group only three gave a history of hemorrhage prior to operation. Thus in 5 instances there was bleeding in varying amounts following operation in which there was no preoperative history of hemorrhage. Gastrojejunostomy alone was done in 44%; gastrojejunostomy and excision or infolding of the ulcer in 80%. Excision alone, pyloroplasty or resection with or without gastrojejunostomy, was the operation of choice in 48%. Gastrojejunostomy alone was effective in preventing recurrence of all cases which gave a history of hemorrhage prior to operation. Hemorrhage may follow

operation in a small percentage of cases, even when an effort has been made to prevent recurring hemorrhage by excision, infolding or ligation of vessels leading into the ulcer. In all cases in which there is a history of repeated hemorrhage, effort should be made to control future bleeding by whatever technic is feasible.

TABLE X.

TOTAL POST-OPERATIVE RESULTS.

Number of letters sent	773
Answers received	600
Food influence on symptoms:	
Ease	2%
Distress	20%
No effect or agrees	78%
Vomiting	15%
Gas	17%
Other symptoms:	
Hem.	6%
Loss weight	11%
Gain weight	65%
Average gain	25 pounds
Constipated	9%
Acid	10%
Ner.	6%
Mo.	1.2%

Post-operative results. Among other things, our inquiries as to the post-operative condition of the patient were directed to the influence of food upon such symptoms as pain, distress, vomiting, and gas. It is noted (Tables VIII., IX., X.) that before operation, control of pain by food was a great factor. It also controlled other symptoms. After operation, there was little necessity for such control. The greatest benefit, according to our statistics, was that, following operation, food could be well borne without producing untoward symptoms and that pain, vomiting and gas were markedly relieved. There was a gain in weight in 65 to 75 per cent. of the cases and constipation was greatly reduced. The most marked post-operative symptoms generally followed in those instances of chronic or subacute perforation of the ulcer in young adults. In these cases the acidity and hypersecretion were especially marked and peristalsis active.

The co-existence of disease in the appendix (16%) or gall bladder (7%) was noted and corrected in 11% of all the cases of duodenal ulcer. In the group of gastric ulcers coincident disease of the appendix (14%) or gall bladder (5%) was present in 9%. In a considerable number of cases, operation was necessary on both organs in addition to the ulcer, with favorable end-results.

Actual recurrence of an ulcer following a properly performed gastrojejunostomy is infrequent,* but it has recurred (in a few instances) when there was no obstruction of the pylorus at the time of the primary operation. In another small group, a secondary operation was necessary owing to the formation of a "new ulcer at the site where the gastrojejunostomy was made, due to heavy silk or linen hanging in the suture line of the gastrojejunostomy."

The patient who seeks relief from distressing symptoms cannot always appreciate a "practical" cure. To cure is relative, and depends on various conditions: (1) General nervous stability, (2) the pathologic condition present, (3) the extent of this condition, (4) the proximity of the lesion to vital tissues, (5) extent of operation necessary to remove the diseased tissue, (6) coincident diseases, (7) the patient's power to react. These factors enter into consideration when treatment, especially surgical, is to be instituted. The patient may be, and often is, freed from disease and life prolonged; yet he may not be freed from symptoms quite distressing. This is not always the fault of treatment, but an inevitable result of the pathologic condition occurring before treatment was undertaken.

* W. J. Mayo: Recurrence of Ulcer of the Duodenum following Operation, BOSTON MED. AND SURG. JOUR., Jan. 29, 1914, vol. clxx, p. 149.

CERTAIN PHASES OF THE PSYCHONEUROSES AND THEIR POSSIBLE TREND.*

BY G. L. WALTON, M.D., BOSTON.

I NEED not review, with this audience, the various steps in the classification and re-classification of these disorders. I need not remind you that thirty years ago the diagnosis "functional" frequently appeared upon our hospital records interspersed with hysteria, hypochondria, nervous prostration and debility, the choice of terms and their application depending largely upon the fancy of the examiner. In the early eighties the "American" disease, neurasthenia, as interpreted by Beard, was received with acclamation on the Continent. When finally the mental basis was recognized as predominant in these conditions, the term psychasthenia was introduced, I think, by Dana. Later dementia precox came to embrace many of the cases which would formerly have been classed under hysterical insanity, a term now seldom used, though it may perhaps still be applied to the cases described by Diefendorf as "distractible and lacking in sound judgment, eager for sensations, and addicted to sensuous enjoyments, with good memory and apprehension, but prone to incorrect interpretation, reaching to fabrication, sometimes accompanied by injury self-inflicted, for the purpose of evidence." This picture falls far short of dementia precox, even though furnishing the groundwork for certain befogged states, deliria, somnambulism and lethargy.

Whether neurasthenia, psychasthenia, or psychoneurosis is used for an inclusive term is perhaps not a very important matter though psychoneurosis seems to me far preferable, in the

* Read at the meeting of the Boston Society for Psychiatry and Neurology, November 19, 1913.

first place because, just as neurasthenia hardly suffices to indicate symptoms that are largely mental, so psychasthenia falls short in that these symptoms are not after all exclusively mental; thus, when a person of this make-up is prone to headache from a moderate degree of astigmatism, to disabling pain in the knee from moderate flat-foot, and to lumbago and sciatica from a mild degree of laxity in the sacro-iliac joint, it is hardly fair to assume that his mind alone is faulty, any more than we can lay to mental weakness his tendency to hay fever, cold sores, ivy poisoning, hives, and balanitis, signs reminding us that the term "thin-skinned" is not purely figurative.

Another objection to psychasthenia is the fact that it seems to suggest a more definite picture than psychoneurosis; not a serious matter if the same picture is presented to every observer. But to illustrate the fact that it is not, I have recently been consulted by two physicians, each in search of a sanitarium for a "psychasthenic." In answer to my question, "What is a psychasthenic?" the one answered, "Why, a man who is so exhausted by mental labor that his thinking processes have come to a standstill." The other answered, "Why, a man who cannot make up his mind whether his clothes are buttoned, whether he has turned out the gas, and the like." These two cases totally differ in etiology and genesis, and as for treatment, the proper prescription for the one is "Loll about," for the other, "Peg along." For one of these two cases the descriptive term "brain fag" has never been improved upon, nor for the other has the French term *folie du doute*. Such distinctive types deserve at least distinctive sub-headings. Unless, indeed, in place of *folie du doute* we freely use the term obsessive psychosis, which will include the doubting folly, an outgrowth of the obsession to make assurance doubly sure.

I need cite no cases to illustrate brain fag. The type is that of the business or professional man, not necessarily by nature psychopathic, who has for a term of years applied himself to onerous and exacting work without rest or vacation. He finally finds that his intellectual faculties refuse to honor further drafts, that he can no longer satisfactorily perform even his routine duties or carry the ordinary details of his work. A comparatively brief rest, if complete (and such a rest a man of this makeup is more able to take without exhausting worry than the congenital psychopath) sets this patient on his feet.

In contrast to this condition, and in illustration of the obsessive psychosis as it presents itself to my mind, I will cite a case shown last winter at a staff meeting at the Psychopathic Hospital.

CASE 1. A bright, intellectual woman, in good physical condition and not tired, had no loss of memory for remote or recent events, no delusions, no hallucinations, and suffered from no other mental defect than that involved in the following symptom, one which was really rather emotional than intellectual. She had been forced by circumstances to leave the house to which she was greatly attached. Her mind had recurred so frequently to the matter that she had become unable to attend to her ordinary duties and had been sent to the hospital for observation. She described the house without exaggeration, it was not wonderful, but exactly what she wanted. Her insight was good. She knew that her attitude was unreasonable, she said it was a crazy idea but that she could not give it up; if she were in that house she would be perfectly happy. Otherwise the mental examination revealed nothing of note except that she was a very careful housewife, very particular about the cleanliness of the children, about her husband's return when he was expected, etc. No previous attack of seriousness was to be made out and no outbreak of depression or exaltation.

We have here to do with a borderland case differing fundamentally from brain fag in that the disability results from inherent psychic defect, the immediate stress being inadequate and incidental. The distinction between her present mental state and the depression of manic-depressive insanity is again a fundamental one. The depression of manic-depressive insanity settles upon the patient after the manner of a fog, though not always with its rapidity. The depression may be aggravated, it is true, by adverse circumstances, but its fundamental peculiarity is that the cloud settles whether circumstances are adverse or favorable. When this depression attains a certain degree of severity, nothing can make the patient happy, the discontent is inherent, a part of his very being. He is incapable of enjoyment until the period is passed during which his spirits are imprisoned. When the load is lightened there may or may not have been an improvement in outside conditions.

In this patient, on the other hand, happiness and gloom depend entirely upon outside conditions. Her unrest may at any time be caused to disappear by the acquisition of that on which she has set her heart, only to return upon the accession of another insistent desire.

Again, I have recently seen a young law student, exceptionally diligent and successful in his studies. He had, however, a moderate degree of astigmatism, and on continuous study his eyes would smart and sometimes he would have the temporary blur that often precedes migraine. His refraction had been properly corrected by a competent oculist. Still he had given up his studies and had made up his mind, regardless of the opinion of the oculist, that there was danger of his going blind. He was joining a gang of laborers at outdoor occupation requiring no near eye work. He was insistent, nevertheless, on knowing today whether he should ever be able to return to the law. This question he found it impossible to allow to rest in abeyance, or to apply himself to the simplest outside proposition. While the obsessive psy-

chosis is distinct from manic-depressive insanity, it is more nearly allied to it than to dementia precox, in that the insight is apt to be preserved and the disorder is largely one involving the emotions. Fear, is perhaps, the commonest underlying emotion, but it may be an overweening desire without fear, as in the classical case of the man who had to rise in the night and flick from the wall a stone which he had the day before, against his inclination, left unmolested.

It is important from the prognostic point of view to have a definite idea of the trend of the psychoneuroses, particularly the obsessive type. Notwithstanding recent pathological advances, I suppose a considerable neurologic contingent today would allow the psychoneurotic to drift as readily into dementia precox as into manic depressive insanity. But the obsessive psychoneurotic, prone to worry about his health, subject to doubting folly, to phobias, and to compulsions of every variety, is peculiarly prone to drift into not only confirmed hypochondria, but into manic-depressive insanity, even including somatic delusions which represent the tendency of the emotional, finally to encroach upon the intellectual sphere. In other words, manic-depressive insanity requires no structural brain defect and offers no insuperable bar to *restitutio ad integrum*. Dementia precox, on the other hand, is essentially a disease of morphologic deficiency, probably with a structural basis not to be attained by the most unbridled exploitation of the psychoneurotic tendency. On the clinical side the ground was cleared for this distinction (1) by recognizing in so-called melancholia atonita a symptom of catatonia; (2) by differentiating the excitement of manic-depressive insanity from the frenzy (*tobsucht*) of the older writers which was quite as likely to mean catatonic excitement or epileptic furor; and (3) by distinguishing the negativism of the catatonic from the retardation of manic-depressive insanity, the analogue of which may be physiologically produced by simple fright.

The fact that the brain of the precox dement is structurally defective does not, of course, preclude or insure against his being also an obsessive. In this case, however, the obsessive make-up is merely an incident in, not the underlying basis of, the disorder.

That manic-depressive insanity may in fact develop from simple psychoneurosis is illustrated by the case of a man of about fifty, whom I have had opportunity to follow for about twenty years. During the first ten years of that time his symptoms were limited to undue sensitiveness, introspection, phobias, dread of society and the like; about ten years ago appeared the first definite suggestion of the depression which tended to more or less regular recurrence, and finally culminated in an attack sufficiently severe to require protracted sojourn in a hospital for the insane. But may a case of psychoneurosis drift thus, of its own inertia, into dementia precox? I think not.

With regard to the theoretical side of the question whether a structual lesion is essential to this disease, Kraeplin's chronic poison resulting from disordered secretion of the genital organs is purely supposititious, and even if it were true, as De Fursac states, that "we have no actual evidence of any pathology of the disease," when he adds that the assumption of such pathological process is purely gratuitous he might with at least equal pertinence apply the term gratuitious to the claim of Kraeplin.

Meyer apparently regards dementia precox merely as the outcome of faulty mental habits or abnormal "reaction types." This author ingeniously analyzes the inadequate reaction by which the mentally inert avoid grappling the various emergencies of life, and indicates that the habitual resort to such reactions may produce dementia precox. He mentions under this heading "hypochondriacal trends, ideas of reference, fault finding or suspicions or attempts to get over things with empty harping, unaccountable dreamlike, frequently nocturnal, episodes, often with fear and hallucinations, leading to strange conduct, such as the running out into street in nightdress, etc." But his hallucinations and nocturnal excursions of the unclad seriously impair his argument, for it is just here that dementia precox is so widely separated from mental inertia and the psychoneuroses as to place it in a totally different category, and when Meyer says that all these happen on the ground of a neurasthenoid development, many of us find ourselves falling out of step.

Almost equally unsatisfactory, from the pathological point of view are the terms used by Gross, Kolper, Wolff, Zweig, Blueler and Dromard, authors grouped by Southard as standing for the non-organic genesis of dementia precox. Such expressions as "disruptions of judgment," "intrapsychic ataxia" and "psychogenic conflicts" are more satisfactory from the articulatory than from the intellectual point of view. On the organic side, the way, already blazed by Alzheimer, Kippel and Shernitte and Sioli, has been materially cleared by Southard, who singles out the pathogenic lesions of dementia precox from the cytological and stratigraphic changes shared by this disease with other mental disorders. Among the findings of Southard I would particularly call attention to such defects as thinning of the corpus callosum, and to cytologic defects underlying gross defect of cortex substance visible already to the naked eye. The question whether such defects are congenital or the result of acquired changes to which that region was susceptible, is of less importance for the present discussion than the fact that they exist, that they preclude *restitutio ad integrum*, and that the analogue has not been found in manic depressive insanity.

The last word has not been spoken on the prognosis of dementia precox, but the percentage of cases has been narrowed to such a degree

that it seems reasonable to assume, as Mitchell intimates, that the residue of recoverable cases is negligible, and that if cure really ensues our diagnosis of dementia precox is at fault. De-Fursac, after stating that a certain number of cases recover completely, quite properly states that these cases are to be accepted only with extreme circumspection. What he means is that many of the apparent recoveries are only relative and that many are mere remissions. May there not be another reason for this circumspection, namely, that some of these cases are not dementia precox at all, and are we justified in assuming that the patient is bound eventually to become demented, because in a certain attack of insanity he has shown symptoms suggestive of dementia precox. To illustrate:

Case 2. A young man, presented at the staff meeting of the Psychopathic Hospital, has been for a number of years inclined to view his own physical condition with undue apprehension, fearful of heart disease and tuberculosis, and is imbued also with the fear that he has ruined his life by early habits. He was brought to the hospital in a state of agitated and anxious depression, restless, unable to eat or sleep, suspicious that whatever happened in the ward had reference to him, insistent that his chest was caved in, that his heart was not beating, that he had no feeling, that his brain was wanting, and the like. In the course of, I believe, a couple of months, the condition passed away and when his case was presented for consideration he showed no mental peculiarity, no defect of memory, attention or judgment, in other words, no disorder of willing, thinking or acting. He was perfectly oriented and with good insight. He realized that his former fears were groundless and that his ideas, though beyond his control, had been nonsensical.

In this case there was and is a tendency seriously to consider dementia precox, a diagnosis which cannot, of course, be eliminated at this stage. But is not quite as probable a diagnosis psychopathic inferiority with predominant hypochondriacal tendency and with a depressive attack accompanied by somatic delusions of the Cotard type?

This young man's future is, of course, to be regarded seriously, inasmuch as he is liable to further attacks of manic depressive insanity and inasmuch as his hypochondriacal tendency is a more or less permanent handicap. But I shall be surprised if the future discloses the mental deterioration of dementia precox.

In the following case I may be demolishing a man of straw, but the diagnosis dementia precox was at one time here also taken seriously into consideration, by both Dr. Paul and myself.

Case 3. This was a man of 22, a *summa cum laude* graduate. He had given up teaching on account of migraine. He shivered in the morning, was hot all night, had a poor appetite and intestinal irregularity, together with various anomalous sensations, for example, as if the back of his head was asleep. He lost flesh, complained of tendency to walk fast, to run down hill and to open his eyes wide. Suddenly one day he felt as if he could not feel. What he did feel was unnatural, for example, after eating it felt to him as if the food went down outside his ribs, and the like. He felt as if he had no muscles. Was depressed, his energy was going from him and no doctor could help him. The blood did not seem right in his hands. There are no thoughts in his mind. The blood flowing through his ears is too "taut." His voice does not seem right, and he fears it is leaving him. There are bursting explosions all over him and there is no consistency to his flesh and no good in him. There is much blood in his nose and his tongue is in the middle of his sternum. He is about to draw his last breath; his bones are on the surface. He was depressed, complained of a feeling of inadequacy, and was an evident sufferer from mental pain. His condition was so serious as to preclude his occupation. The condition gradually disappeared and today, five years later, he is at work successfully teaching and showing no sign of mental defect.

The following case is really much more suggestive of dementia precox which is still, I think, the prevailing diagnosis among the alienists interested.

Case 4. A woman of about 30, accused her employer of an indecent attack. She made no outcry, she said, but it seemed as if her throat was closed. She continued her work for a week as usual, because it "interested" her. At the end of this time she consulted a physician who referred her to a lawyer. It then appeared that some three years before, she had been an inmate, for nearly a year, of a hospital for the insane, with a provisional diagnosis of dementia precox, and a second choice of catatonia of autotoxic origin. From the hospital records it appears that she was committed on account of talking excessively about a certain work she was to undertake, thinking that the newspapers were talking about her, becoming restless, confused, irritable, then mute and resistive, asking for food and then not taking it, losing weight. During her stay in the hospital she was resistive, would not respond to questions and refused to eat, seemed at times dazed and unwilling to talk, suspicious and confused, apathetic, sometimes excited and struck others; at one time said the food was poisoned; was untidy. After about nine months began to improve. Took more interest and did ward work. Was suspicious of the physicians and sometimes rough with other patients, but less untidy. No hallucinations, well oriented and with no anxiety. Not resistive, but is said to have had the attitude of dementia precox, antagonistic and evasive. Further investigation of her history outside the hospital disclosed the fact that she had made a demand upon another, claiming indecent assault. Later she complained of injuries at the hand of another. She went to a third lawyer with a case, the nature of which is unknown. This lawyer had had two or three more claims of hers against other men for assault. While variously employed, she had recurring trouble with others, who were discharged through her complaints, but afterwards reinstated at her request, only for the trouble to recur.

Examination showed a robust, well-developed, strong and active woman, revealing no mental defect

beyond the suggestion that she lacked continued application, as shown by the fact that while she could subtract 7 from 100 promptly and correctly, also 7 from 93, and 7 from 86, when asked to continue the process she carried it only to 57 (a wrong result) and showed utter lack of further interest. It also seemed that in the past six months she had taken places with five different employers.

Here, then was a third case which might very well be included in the statistics as one of dementia precox with several years' interval without mental deterioration, but to my mind it is very doubtful if the case should be included under dementia precox at all. This young woman possesses highly developed sexual proclivities with a hysterical groundwork, a tendency to find a sexual content in every incident and to fabricate and to exaggerate, if not imagine, her own physical ills. I hesitate to characterize the attack while in the hospital, but in view of the subsequent history I am neither inclined to regard it as dementia precox or acute intoxication. The diagnosis hysterical insanity should perhaps be taken into consideration, with an unusually prolonged period of confusion and befogging of the intellect. At all events, I should rather regard it as an outgrowth of her psychopathic inferiority than as of infectious origin. If I were obliged to designate her present condition, I should feel more inclined to ally it to high-grade imbecility than to dementia precox. This was perhaps an unfortunate case to select for illustration inasmuch as the diagnosis is not clean cut. The acknowledgment of this fact, may, however, tend to absolve me from the accusation of diagnostic absolutism.

Especial care should be exercised in choosing between the diagnosis manic depressive insanity and Kraepelin's "maniacal" or "periodic" form of dementia precox. Thus: I have been recently consulted regarding the testamentary capacity of a man, who, at the age of seventeen, sixteen years before making his will, was treated for six months in a hospital for the insane. This attack was characterized, in brief, by suicidal depression, excitement with violence and profanity, ideas of reference, confusion and non-recognition of friends. The prior history and habits were not of significance. The case was regarded as one of dementia precox. Recovery followed with one attack of depression four years later, lasting two months. Otherwise the mental history has been uneventful, a chosen line of professional work having been meantime learned and successfully practiced.

The diagnosis in such cases is not a purely academic question, but one of practical prognostic importance. Whatever ground we may take as to the future usefulness of the litigious nymphomaniac, are we bound to regard a successful business or professional man as liable to dementia because of a single outbreak, occurring, perhaps, five years ago? I think such patients should rather be given the benefit of the doubt.

CONCLUSIONS.

It would be desirable in the sub-classification of "Neurasthenia," "Psychasthenia," or "Psychoneurosis" (preferably the latter) more freely to use the terms Brain Fag and Obsessive Psychosis, and to recognize the fundamental difference between them.

While the sufferer from obsessive psychosis may drift into chronic hypochondria, or into manic depressive insanity, he will become a case of dementia precox only if he has the inherent brain defect which limits development and predisposes to deterioration.

Prognostic injustice may easily be done by making the diagnosis dementia precox on the basis of a single psycho-pathological outbreak with symptoms suggesting that disease.

SUGGESTIVE TREATMENT IN DISEASES OF CHILDHOOD.*

BY WILLIAM W. HOWELL, M.D., BOSTON.

I WISH to present to you this evening a branch of the healing art which has always been associated with medicine and which even antedates by centuries any scientific or practical knowledge of drugs. Long before man had knowledge of drugs he tried persuasive measures. Hence psychotherapy, mental healing, suggestive treatment, or whatever name one may apply, is the older method of treatment. Plato said: "The office of the physician extends equally to the purification of the mind and body. To neglect the one is to expose the other to evident peril."

Physicians have been loath to use such methods for they constitute the armamentarium of charlatans and quacks, but I hope to show that if we approach the subject fairmindedly and consider actual results, we may be convinced of its scientific value. I have limited myself to suggestive treatment of children, for it is only with children that I have tried to gain any real working knowledge of suggestion. However, I believe the principles to be much the same in old or young.

The older methods of medical instruction dealt with disease and its treatment, not with an individual sick with a disease, not considering the individual's peculiarities, idiosynerasies, and effects from his nervous system. Czerney gives it as his rule not to treat any kind of children's disease without considering the peculiarities of the child. The nervous system of children is very sensitive, easily unbalanced, and susceptible to outside influences, hence psychic disturbances are extraordinarily frequent, and for the same reason easily influenced and cured. A child of psycho- or neuropathic parentage, even at very

* Read before the Norfolk District Medical Society, Boston, October, 28, 1913.

early age may show increased susceptibility to nervous derangement, not merely as pure psychic disturbances, but as psychic manifestations in the course of definite diseases.

By psychic disturbances are understood all those manifestations which have their foundations in the imagination of the individual and may have to do with any organ or function of the body. Consequently by suggestive or psychic therapy is meant any treatment which works on the imagination of the individual. Through our words and deeds we have a marked influence on the feelings and imagination of the child, which in turn exert a mighty influence over all bodily function.

In order to understand the principles of suggestive treatment it is necessary to understand the mechanism of the mental machinery which produces psychic disturbances. To quote from Hamburger: "Any kind of irritation or stimulus occurring one or more times loosens in an individual an unconditional reflex, that is, that the individual for reasons of a congenital susceptibility of his nervous system answers to this stimulus with a definite reflex. If the reflex has occurred several times, if the remembrance of it is active on account of accompanying conditions, then it is possible through voluntary or involuntary reproduction of the stimulus, which is remembrance, automatically to cause the same reflex." It now appears that to understand the mechanism of these processes it is necessary to explain the workings of unconditional and conditional reflexes. All our bodily actions are dependent upon reflexes, which means that a stimulus applied excites the centripetal path to the central nervous system, is then carried over to the centrifugal path, and the action or reflex takes place. A definite stimulus is always answered by the same action, and hence the reflex is called unconditional, and such are the reflexes of ordinary life. It is known that these unconditional reflexes may be influenced by outside factors or psychic factors, and then become conditional reflexes. The experiments of Pawlow, though primarily performed to explain certain digestive phenomena, help to explain the doctrine of unconditional and conditioned reflexes.

Pawlow showed that when a dog is given food immediately the salivary and gastric glands become active. This is an unconditional or unlimited reflex. However, it is not necessary that the dog actually get food, the sight or smell of it being sufficient for the dog to form the conclusion that he is to have something to eat and the reflex takes place. The food, or the sight or smell of it is the unconditional stimulus, the action of the glands the unconditional reflex. Further experiments show that this reflex can be influenced in various ways. If just before the dog gets food a bell is rung and repeated for several days he gets the idea that when the bell rings food is coming, and soon the mere ringing of the bell suffices to excite the reflex. This is a conditional or by some called limited reflex, for if after repeatedly ringing the bell food fails to appear, the glands do not act and the reflex fails.

An understanding of the conditional or limited reflex is not sufficient to explain the mechanism of psychic manifestations, but there is necessary an explanation of the statement from Hamburger, which is "for the discharge of the limited reflex it is in many cases not necessary that the definite stimulus enter, but that the conscious or unconscious remembrance of it may suffice." An understanding of this doctrine clears up a great many of the socalled functional or psychic diseases. An analysis of ordinary fainting attacks, which are pretty generally attributed to reflex cerebral anemia, explains this doctrine. In an individual with exceedingly flexible blood vessels and susceptible nervous system, a severe fright may cause cerebral anemia, paleness, loss of consciousness and a faint. This is an unlimited reflex for the person so constituted must react with a faint. This is an unlimited reflex unless he has had previous attacks, when the remembrance of these previous attacks gives anemia more easily, and we are then dealing with a limited reflex depending on the remembrance. The slightest fright now is able to cause brain anemia, and even the remembrance alone; therefore, the pure psychic reproduction suffices to cause an attack. Such a remembrance may run entirely consciously or subconsciously and cause a reflex anemia. The greater the practice or the more often repeated, the more the disease picture approaches what is known as simulation or hysteria. The less consciously the action runs the more difficult is it to recognize the psychic character of the disease, and indeed it becomes almost impossible to find the cause of the reflex. In such a case the reflex of course cannot be stopped by removing the original stimulus, but can be influenced through an indirect means by interrupting the discharge of the action. Just so in Pawlow's experiments if the dog's attention while eating is distracted, for example, by the sight of a cat, the chain is broken and the reflex, which is the digestive action, is interfered with.

It must be remembered that in children there is always something real as a foundation for their psychic disturbances, which is a physical or psychic trauma or an attack of sickness leaving a deep mental impression, for example, apparent sickness with malaise, loss of appetite in schoolchildren after unjust treatment by teachers, paroxysmal cough after a true attack of pertussis, the many habit spasms, and so on.

As an example of physical trauma causing a psychic disturbance, I will cite the following case:

CASE 1. A healthy boy of thirteen years was attacked by a dog and in some way was struck in the scrotum, resulting in severe pain and involuntary micturition. The boy thought he was severely injured, but told no one as he was ashamed. He suffered from frequent micturition, wet his bed, at times wet his clothes during the day, and could

not go through a session at school without going to the toilet twice. His mother punished him and by comparing him to his younger brother who was clean, increased his shame. The teacher kept him after school for going too often to the toilet. In every way his mental impression was aggravated. This went on for six weeks, when he consented to see me. Careful examination revealed nothing abnormal locally or in the urine. Positive assurance that he could be cured and that he would not wet again if he took some bad medicine resulted in complete cure.

To tell him that there was nothing wrong and that he was silly might have failed. The promise of cure and the medicine to remind him of that promise effected a cure.

That psychic trauma may cause symptoms simulating disease is shown by the following example:

CASE 2. A girl of six years came to the outpatient department of the Infants' Hospital in May, 1913, with a diagnosis of nocturnal epilepsy. Almost every night at 1 a.m. she would become restless, might wet the bed, or waken with a cry, look wild, excited and go off to sleep. Never any day attacks. This dated from a night a year previously when she woke about the same time in the night and went to the toilet. As she opened the toilet room door a large cat sprang out, giving the child a fright. Assurance that she was to be cured and that the cat never could come again, and she must take some bad medicine to be cured, prevented the attacks for a week. The mother could not come to the clinic for two weeks and during this time the attacks returned. Renewing the assurance and a stronger medicine stopped the attacks.

Disease may be affected in two ways psychically, may be aggravated by psychic disturbances, or psychic conditions by lowering the resistance may allow disease to set in. The following case will illustrate both of these points:

CASE 3. A girl of twelve years of nervous parentage and disposition had a slight throat operation which left her extremely nervous. A few days later she went to the seashore for a vacation. On the first day she remained in bathing till she was overtired. The next morning she went for a long tramp, was overheated, hysterical, thought she could not breathe, and fainted. She was in bed several days, and then became well enough to go down to the shore and walk about, but still apprehensive that she was about to faint or lose her breath. A week later twitching of the face and right arm and violent action of the respiratory muscles began. I saw her later with a typical chorea and later an endocarditis developed. The psychic trauma of her fainting and loss of breath helped bring on her chorea and then made it worse.

That disease may cause psychic phenomena, the paroxysmal character of any bronchitis cough after a true pertussis, is an example, the remembrance of the original pertussis causing all subsequent coughs to simulate a whoop, and it is a very difficult matter to decide whether it is a second attack or a simulation. So with chorea—it is one of the hardest medical problems to solve, if a second choriform attack is a relapse, a new infection, or a psychic reproduction.

There is another type of case which is best classed and treated as psychic. I mean disturbance taking place in the sleeping hours, as eneuresis, night terrors and somnambulism. That these processes are due to dreams there can be little doubt, but as they occur in the early hours of the night when sleep is heavy, the dream itself is not remembered. It is very probable that a full bladder causes a dream that the child is on the stool or has a diaper on, and urination takes place and he wakens to find himself wet, but he has no recollections of the dream, or he lives through some fright in his dream and has night terror. That this is true is not possible of proof in all cases; still there are enough cases in which the children remember the dream to enable us to establish the fact. Another proof that these processes are psychic in character is that it is possible to influence them by suggestion in the waking state. It must be remembered that I am speaking of cases in which there is no definite organic lesion to account for the eneuresis or night terrors, for such lesions occurring in highly strung children give nocturnal eneuresis and night terrors which are not open to suggestive treatment. These would be analogous to unconditional reflexes. After lesions have been cured, as phimosis or pyelitis in eneuresis, or fright in night terrors, the conditional reflex due to the remembrance may remain and may then be influenced by suggestion.

There are three methods of treatment, the cathartic method of Freud, otherwise known as the etiological or analytical method, the suggestive or deviation method, and, finally, the method of hypnotism.

The last method, or that by hypnotism, I have never tried and from the cases in which I have seen it tried I am not sure that it is devoid of danger. With the other two methods I have had good results and I can see no need of the more difficult and dangerous hypnotic method.

By the cathartic method is meant the broad meaning of catharsis,—that is, purification. It removes from the child's life the influence or irritant giving rise to his psychic disturbance which has undermined his health. In this sense it is not suggestive treatment, for by simply removing the cause cure results, but it is psychic in that the cause works on the child's mental or psychic side and thus causes sickness.

I can best illustrate by the following case:

CASE 4. A girl of thirteen years, bright and very ambitious. Her father was unreasonably eager that she make good progress in school and in her social affairs, and indeed was quite severe. The child was not overworked and had time for exercise. She craved praise for her work, but instead received no encouragement from her father and nothing but censure for not getting even better marks. When playing the piano at a social event she made a mistake. The father would not speak to her for a week. Under such strain she lost her appetite, became pale, menstruated twice monthly, was very listless and failed to keep up with her classes. A

sharp talk with the father and removal to another school brought return of health and good progress in studies.

The case is psychic in that the child's physical state resulted from her mental unhappiness, and cure resulted by catharsis, that is, by removing the cause.

The suggestive or deviation method is applicable to cases where it is impossible to analyze the case or to remove the cause, or in which the cause has ceased to be active, but merely the remembrance produces the reflex. The mechanism of the method is somewhat as follows: the physical or psychic trauma or the remembrance of it starts the reflex, which runs its usual course up to the point where the child remembers consciously or unconsciously the suggestive cure, when the course is sidetracked and the reflex fails to take place. Exactly as in Pawlow's experiments with the dog when he saw the cat, digestion ceased, the cat being the deviation cure. When giving the suggestion the doctor must be kind but firm, and it is not wise or necessary to create in the child any idea of punishment. The doctor asserts to the mother in the child's presence or directly to the child that absolute cure will take place, and gives some kind of medical or mechanical treatment. It is usually best to give some unpleasant medicine or unpleasant mechanical treatment as the faradic current. It must be something which makes the child remember the words promising cure, and should be repeated often enough to keep up the remembrance. This case will suffice to illustrate:

CASE 5. A little girl of three and one-half years, suffering from enuresis both day and night. Examination of the urine showed many pus cells and highly acid reaction. Clearing up the pyelitis did not cure the enuresis. Positive assurance that she could not wet again and Tr. of Nux stopped the enuresis by day but not at night. Two applications of faradism at bedtime stopped the nocturnal enuresis.

Another class of cases, the various ties or more properly called habit spasms, readily yield to suggestive treatment. In very young children faradism over the affected muscle if persisted in will bring cure in almost every case. In older children, sitting in front of a glass till the spasm occurs, and then repeating it voluntarily several times, often cures. I am inclined to think it is not so much the transformation of an involuntary motion into a voluntary one, as it is the subconscious remembrance of sitting in front of the glass, which produces a cure.

I believe that in many infectious and organic diseases we may be able to relieve much suffering by judicious use of psychic treatment. This opens up a dangerous field and one closely allied to quackery but it seems to me it cannot be quackery if by suggestion definite and permanent good results. A brilliant example of the harm that may be done is the real but temporary improvement in tuberculous cases from a recently exploited cure.

There is one infectious disease in which I have seen marvelous results, not in my own experience but at the Policlinic in Vienna. I speak of pertussis. After the infectious period of from four to six weeks the whoop is a habit and can be stopped by suggestive therapy, even though a bronchitis remains. The whoop recurring with subsequent bronchial or pharyngeal trouble can be stopped with ease. Rachford says in his "Diseases of Children," "The psychic treatment of whooping cough is of importance in children that are old enough to be influenced." Perhaps I lay myself open to criticism when I say that the results reported from the use of vaccines in pertussis depend on the psychic effect of the weak, but I must believe it after what I have seen from suggestion by faradism. The same may be said of chorea after the infectious period is over, and certainly so of the recurrent choreiform movements not due to true chorea. In the case of chorea mentioned above, the child was more comfortable when through suggestion she became convinced that she could breathe and was not going to faint.

At what age results may be expected from suggestive treatment is an open question. I believe in very early infancy there is some response to suggestion. A baby of six weeks may be trained to have a daily movement on a bed pan. A young baby taken from the breast may refuse the bottle. After a few tube feedings he will take the bottle perfectly. There may be some doubt about these cases but in both examples they have received an impression of some kind with a perfectly definite result. After three years, suggestive treatment is perfectly possible in most cases.

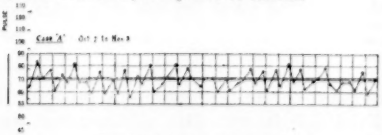
I believe that all of us underestimate the value of psychic treatment and that we do not consider enough the nervous makeup of our patients. The man who in treating children is kind but firm, has the knowledge of child nature and the tact to apply such knowledge, can do much to relieve suffering, not only mental, but also that bodily suffering which depends on psychic impressions.

LEPROSY: THE PULSE AS A POSSIBLE INDICATOR OF THE PROGRESS OF THE DISEASE. (A PRELIMINARY NOTE.)

BY JAMES A. HONEIJ, M.D., PENIKESE, MASS.

Penikese Island Hospital.

IN all febrile diseases and especially in tuberculosis, there is an evening rise in temperature, pulse rate and respiration. In leprosy this usual condition is reversed, so far as the pulse rate is concerned. In the morning the pulse rate is higher than at evening; often markedly so. That this condition is not due to the greater morning activity of the patient or to atmospheric changes has already been determined.

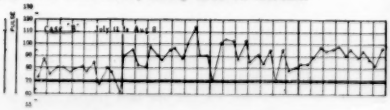


Great care has been taken in the making of these records, and as far as possible, surrounding conditions were alike, (morning and evening): An enforced rest of half an hour previous to taking the pulse and various precautions were observed and controls made to exclude errors. To exclude thermometer faults, all thermometers were compared and adjusted. The patients were at all times under the supervision of a nurse.

This clinical observation was carried out with sixteen patients, during the year 1913, but with greater care after July 1st. This heretofore undescribed phenomenon occurs in the majority of cases, and especially in those patients who are in an advanced, active stage of the disease. The same condition is present during febrile disturbances. One patient shows only anesthetic lesions and whether the disease is actively progressive cannot be determined for some time. From all appearances, this patient has failed during the past year, but as she is one of only two anesthetic cases, it makes the matter rather difficult of solution. All the other patients are of the tubercular type.

Some changes have been observed in temperature and in respiration, and may be an indication of a similar although less marked change than the pulse; but just how important these changes are will not be dealt with in this preliminary report. As the title indicates, I have considered the change in morning pulse rate as an index to the condition of the patient, as a study and comparison of the charts will show.

The charts are for a period of one month showing morning and evening pulse rate in each ruled column. Seventy has been considered the normal pulse rate, consequently there is evident at once the common higher pulse rate in leprosy.

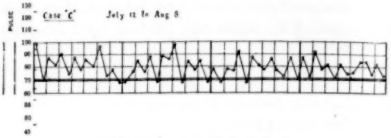


CASE "A". Tubercular type; early case; good physical condition; fairly free of lesions.

CASE "A." Oct. 7 to Nov. 3.

Chart showing fairly normal pulse for comparison with those showing morning rise.

CASE "B". Tubercular type; early case; good physical condition; fairly free of lesions.

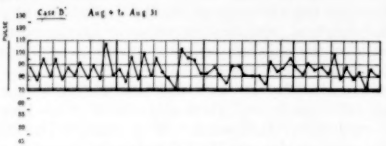


CASE "B." July 12 to Aug. 8.

Chart showing greatly varying pulse, with tendency to change.

NOTE: Patient is a highly nervous individual. Temperature normal. Respiration shows similar tendency as pulse.

CASE "C". Tubercular type; most advanced case; poor physical condition; various and numerous lesions.

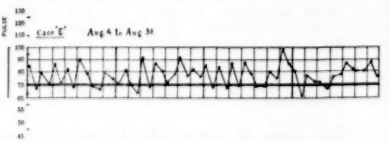


CASE "C." July 12 to Aug. 8.

Chart showing typical change in morning pulse rate.

NOTE: This patient is for the greater part of time in bed in the last stages of the disease. Temperature normal. Respiration shows marked tendency to similar change in morning rise of pulse. This patient shows same condition during whole period observed.

CASE "D". Tubercular type; advanced case; fairly good physical condition; various and numerous lesions.

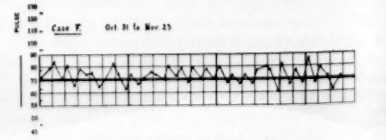


CASE "D." Aug. 4 to Aug. 31.

Chart showing most typical morning change in pulse rate.

NOTE: Patient reacts quickly to any marked physical effort. Normal temperature. Respiration shows slight similar change. During length of period under observation pulse change is regular for all months.

CASE "E". Tubercular type; advanced case; poor physical condition; various and numerous lesions.

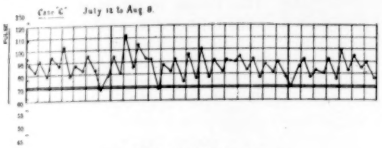


CASE "E." Aug. 4 to Aug. 31.

Chart showing very typical morning change in pulse rate.

NOTE: This patient is a highly nervous individual. Daily health condition varies considerably; temperature slightly above normal as a rule. Respiration shows marked similar change.

CASE "F". Mixed type; advanced case; poor physical condition; fairly numerous lesions.

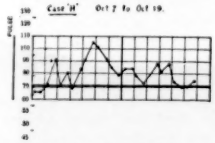


CASE "F." Oct. 31 to Nov. 23.

Chart showing fairly typical change in morning pulse rate although on normal lines.

NOTE: Patient also presents signs of lung tuberculosis. Daily health condition varies considerably. Temperature and respiration show apparently immaterial changes.

CASE "G". Anesthetic type; questionable activity; good physical condition; anesthetic lesions.



CASE "G." July 12 to Aug. 8.

Chart showing morning change in pulse rate but of "highly nervous" type.

NOTE: Patient easily excitable; chart shows "nervous" pulse; Temperature slightly above normal as a rule. Respiration shows some similar changes. A possible exception to tentative conclusions made regarding value of pulse readings.

CASE "H". Anesthetic type; stationary case; good physical condition; anesthetic lesions only.

CASE "H." Oct. 7 to Oct. 19.

Chart showing pulse during febrile disturbances with tendency towards change in morning rate.

NOTE: Patient here showed the usual febrile change with its accompanying symptoms as seen in leprosy; up to this time patient had been practically free from signs of disease excepting the original permanent lesions due to anesthetic leprosy.

In analyzing the result of this work and the frequency of the occurrence of this phenomenon for five months, the following facts have been obtained.

a. In the six patients who present this change in more than three-fourths of the time noted, one has died, four are in the most advanced stages, and one is an exception, being an anesthetic case. The charts of five of these patients of this group are presented with this paper.

b. Three cases demonstrate the change noted in more than one half of this period. In the second of these patients there is a marked increase agreeing with the general condition, during the last three months and in the third during the last two months. In the other case there is a marked decrease in the last two months agreeing most strikingly with the recovery of the patient from a prolonged and serious condition.

c. Three cases show this change during more than one fourth of the time, and in two of these cases there is a still greater increase during October and November. Clinically these patients are in an advanced stage.

d. Four cases, all in the early or less serious stage of the disease gave negative results during July, August, September, and with one exception during October and November. The exception shows the tendency towards the change in higher morning pulse rate during one half of these two months.

This reversal of the usual febrile diurnal pulse may prove by further investigation to be of real prognostic importance. And, in the hope that other workers may verify this observation, this paper is now presented.

ILEAL STASIS.*

BY HAROLD W. BAKER, M.D., BOSTON.

Surgeon to Out-Patients, Free Hospital for Women, Brookline, Mass.,

AND

DONALD V. BAKER, M. D., BOSTON.

METCHNIKOFF has rightly called the large intestine, the cesspool of the human body. In his remarkable work, he calls attention to his researches bearing upon the effect of the existence of such a cesspool in the body. He has shown that autointoxication, decline and senility, are due in large measures, to absorption of toxins (pathological to be sure) from the large intestine. Since he called attention to these facts, we have discovered that such pathological absorption can only occur to a harmful degree, when the contents of the large intestine become unduly stagnant. But, however harmful such may be in any individual case, there are much more disastrous effects when stasis occurs in the small intestine. I will confine this paper to a consideration of ileal stasis, therefore, as it appears the more important.

Stasis in the ileum, is usually caused in four ways, by chronic appendicitis, by an ileal kink (as that of Lane[1]), or by a congenital membrane (as that of Jackson[2]), or by an incompetent ileo-caecal valve[3]. More than one of these causes may be present and at times a kink seems to have formed more or less as a result of a chronic appendicitis. As a general rule, the incompetency of the ileo-caecal valve is preceded by one or more of the others. Conversely, the first three usually result in the last. Most of the symptoms of this stasis, are due to this failure on the part of this valve, and so we must review the normal anatomy and physiology of the caecal region, in order to understand the condition.

The intestinal peristalsis, is broken or interrupted in two places—at the pylorus and again at the caecum. The pylorus has a true sphincter, whereas the ileo-caecal valve has more of a valve, due to its pushing into the caecum. It has also a sort of sphincter, in that the habenula[4] or taeniae coli do not invaginate into the caecum with the ileum, but are stretched tightly across the invaginated ileum's base, to preserve the intussusception, as it were. Kellog[5] believes the integrity of the habenula is an important

* Read before the Norfolk South District Medical Society, Boston, Mass.

factor in the normal physiology of the valve. In the dried specimen, the upper segment projects further into the caecum than does the lower. Thus, the aperture lies between the edge of the lower segment and the under surface of the upper. Symington[4] pointed out, that the efficiency of the ileo-caecal valve is due to the obliquity of the invagination and, as in the case of the ureter piercing the bladder wall, such a mode of entrance is probably enough for the potency of the valve.

Normally putrefaction never takes place in the small intestine. According to the best authorities only the carbohydrates are fermented by the bacteria of the small intestine. Digestion of the food intake, is practically complete by the time the terminal ileum is reached, which usually occurs in from two to five hours. At least 85% proteid, 90% fat and 98% of sugar are assimilated by the small intestine. The ileo-caecal valve has three purposes:

1. To hold back undigested food.

2. To pass unused intestinal contents, which are nine tenths water, into the colon for dehydration.

3. To prevent regurgitation of the contents of the colon into the ileum—Cannon[5] has shown that reverse peristalsis occurs normally in the ascending colon and caecum and the patency of the valve is very important, in order to prevent caecal contents being forced back into ileum.

Cannon, Case and others, have shown, by means of the x-ray, that this valve not only prevents the return of material from the colon into the ileum, but that it also regulates the onward movement of the food stream from the terminal ileum into the caecum. In this way, it is very much the same kind of sphincter-valve as the pylorus. Thus, normally, no intestinal stasis may occur, but under pathological conditions, as we have already pointed out, it may occur from four causes.

Perhaps the most common cause of stasis, is a chronic appendicitis (Plate 1). Adhesions readily form about the appendix and caecum, and they may cause stasis in several ways. Directly, through partial obstruction to a greater or less degree stasis may occur. Or, indirectly, they may cause overdistention of colon and terminal ileum, with the resultant rupture of the habenula, the destruction of the normal intussusception of the ileum into the caecum and a worthless ileo-caecal valve. The results of this we will refer to later.

A Jackson membrane (Plate 2) may cause stasis also. It may do so either by constricting the ileum or ileo-caecal valve in such a way that food cannot pass into the caecum, or by causing incompetency of the valve itself.

The presence of a Lane's kink (Plate 3) usually results in ileal stasis, because it shuts off the lumen of the gut, mechanically. It may, however, constrict the ileum in such a way as to cause no real mechanical obstruction, but rather pull the ileum back out of the caecum and thus destroy the competency of the ileo-caecal valve. The ileum is no longer kinked, as the added length prevents such mechanical obstruction, but stasis results just the same.

An incompetent ileo-caecal valve (Plates 4 and 5) is a very important cause of ileal stasis and often results from any one of the other three causes, as we have pointed out. In fact, the majority of the pathology of ileal stasis, is due to the failure of this valve. It may occur independent of the other causes, for overdistention of the caecum or terminal ileum from gas or food, may result in obliteration of the normal intussusception of the ileum into the caecum.

As a result of the failure of the ileo-caecal valve, the food is allowed to reach the colon with digestion incomplete. Diarrhoea may result easily, with malnutrition. On the other hand, the reversed peristalsis in the colon, propels the contents back into the ileum, with their millions of bacteria. Putrefaction and toxic absorption take place, where normally none occurs. Gradually, this involves more and more of ileum and jejunum and the worst effects of the regurgitation are registered on the duodenum, gall bladder and stomach[6]. In the most of such cases, the duodenum is found markedly distended and in very advanced cases, the congested mucosa results in tremendous peristalsis with gnawing pain and distention in the duodenal region. Such duodenal distention may then be accompanied by gastric residue.

The duodenum is the most sensitive point in the alimentary tract. It is not at all strange, that with the congestion and ulceration due to bacterial invasion from the colon, the biliary and pancreatic duets should likewise suffer. Cholecystitis, pancreatitis, gall stones and even cancer, may then result.

The symptoms of this stasis are many and varied. They may be those of chronic appendicitis, Jackson's membrane[7], Lane's kink[1], gastric or duodenal ulcer or of autointoxication.

With the increasing skill of trained Roentgenologists, the positive diagnosis, depends on x-ray examination to a very large extent. Any of the symptoms as outlined, should always have an x-ray examination. The bismuth meal should all be beyond the ileo-caecal valve, in from 6 to 8 hours after ingestion. Not only can the degree of stasis of the ileum be diagnosed in this way, but in the majority of cases the cause, as chronic appendicitis, Lane's kink, Jackson membrane and incompetency of the ileo-caecal valve. Jordan, Case, Brown, Dodd and others, report cases of incompetency of the ileo-caecal valve, when bismuth enemata were used, in which the bismuth has passed the valve and has proceeded as high as the jejunum and duodenum.

The treatment may be either medical or surgical. In cases where constipation seems to be the cause alone, bulky food should be the only diet and albolene, agar-agar, etc., should be given. Three stools a day should be required,

PLATE 1.

Ileal Stasis Due to Chronic Appendicitis.

Diagnosis made by x-ray examination, Dr. Walter Dodd, and confirmed at operation.

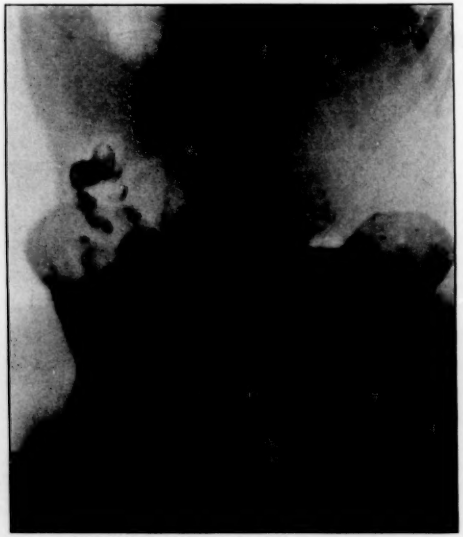


PLATE 2.

Ileal Stasis Due to Lane's Kink.

Diagnosis made by x-ray examination, Dr. Percy Brown. Operation: Lane's kink freed, ileo-cecal valve repaired. Four months later no recurrence of symptoms.

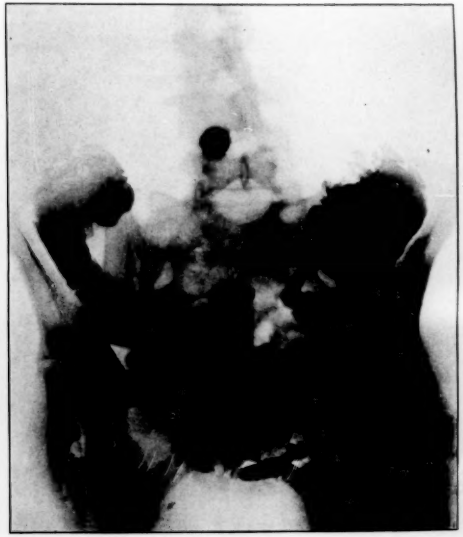

PLATE 3.

Ileal Stasis Due to Jackson Membrane.

Diagnosis made by x-ray examination, Dr. Percy Brown. Operation: Membrane severed, raw surfaces covered with omental graft. One year after operation no recurrence of symptoms.

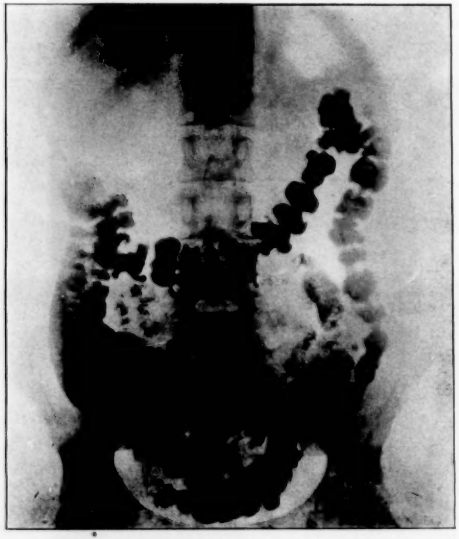

PLATE 4.

Ileal Stasis Due to Incompetent Ileo-cecal Valve.

Diagnosis made by x-ray examination, Dr. Walter Dodd. Operation: Ileo-sigmoidostomy, nine months after operation, no recurrence of symptoms, with gain of twenty pounds.

PLATE 5.

(Bismuth Enema.)

Ileal Stasis Due to Incompetent Ileo-cecal Valve.

By courtesy of Dr. Walter Dodd.

preferably after meals. The protein intake should be reduced and the carbohydrates increased, in order to decrease putrefaction. The bacillus bulgaricus may be fed to help decrease autointoxication. Kellog's results[3] are most gratifying after an average treatment of 48 days, for 86% are cured or nearly so.

The surgical treatment is indicated where the medical has failed and always where a true lesion is known to exist. Membranes and adhesive bands must be freed and the raw edges covered with peritoneum, so that they will not reform. If the ileo-caecal valve proves to be incompetent, it should be repaired by invaginating the ileum into the caecum and stitching it there and by stitching the torn edges of the habenula. At time of operation the efficiency of this valve may easily be determined by stripping back the contents of the ascending colon and caecum to see whether it will pass back through the ileo-caecal valve into the ileum. Then after repairing the valve, test the efficiency of your work in the same manner.

In case these procedures cannot be done we must resort to ileo-sigmoidostomy. In doing this operation, the ileum should be obliquely invaginated into the sigmoid, a short way, in order to construct a competent ileo-sigmoidal valve.

Any patient with symptoms of chronic constipation, autointoxication, suspected kinks or membranes, should have a thorough x-ray examination by an expert Roentgenologist. When pathological conditions are found present they should be treated medically or surgically.

REPORT ON PEDIATRICS.

By Thomas Morgan Rotch, M.D., Boston,

and

Charles Hunter Dunn, M.D. Boston.

ACQUIRED CARDIAC DISEASE IN CHILDHOOD, RÉSUMÉ OF RECENT LITERATURE.

Göppert[1] discusses the diagnosis of acquired cardiac disease in early life, with special reference to the frequency of evidence which might lead to an erroneous assumption of a cardiac defect. Among them are the heart-lung murmurs which appear and disappear during the examination and become inaudible if the breath is held in the expiratory position. He declares that systolic murmurs at the pulmonary orifice are so frequent that they are an almost normal occurrence in the development of the child, and only a small proportion of them are associated with anemia and malnutrition. In Göppert's experience, a slight impurity of the first sound has frequently led to the mistaken assumption of an endocarditic murmur, and a reduplicated second sound is liable to cause unwarranted concern. If no other changes can be discovered in the heart, these murmurs may be regarded as accidental. The high pulse rate frequent in normal children is also apt to be misleading. If the pulse is good, Goppert has the child run up two flights of stairs and examines him again as soon as he comes down. With normal conditions the child is only a little out of breath, and the increased pulse rate returns to the normal in about three minutes and keeps strong throughout. Göppert warns against the erroneous diagnosis of myocarditis when the pulse is slow, and occasionally intermittent. This form of irregularity is comparatively frequent in children, possibly from intestinal reflexes or growth anomalies. The stair test, in these cases, is followed by acceleration and normal regularity of the pulse, but the irregularity returns as the effect of the test subsides.

Shlieps[2], takes up the question of the disappearance of one heart sound, which occurs in infants with severe nutritional disturbances. There has been much discussion as to whether the remaining sound is the first or the second. The question is of practical importance from the point of view of treatment, because if it be the first sound which disappears, therapy should be directed toward increasing the contractile power of the heart, whereas if it be the second, treatment should concern itself with the blood pressure. Shlieps believes it is the first, or muscular heart sound which disappears, and gives the following reasons: 1. We know that during severe cases of acute infectious disease in older children, it is the first sound which disappears. 2. The poor nutritional condition of the skeletal musculature would suggest a similar condition in the heart muscle. 3. If the blood pressure is normal, diminution of the clearness of the heart sound would suggest that it is the first sound which grows fainter. 4. The remaining sound is more distinct at the base than at the apex. 5. The administration of cardiac stimulants, such as camphor, makes the sounds clearer, even when the blood pressure is normal.

While Shlieps' conclusions may be correct, we cannot agree with all the reasons given. Recent work has clearly shown that in fatal cases of acute infectious disease in older children, the cause of death is lowering of the blood pressure much more frequently than weakening of the muscular power of the heart. Also the results of blood pressure work in infancy have not yet

been sufficiently satisfactory to permit the drawing of any valuable conclusions on this basis. Shlieps' second reason, the poor nutritional condition of the muscles in general, seems the most suggestive.

Nobecourt and Voisin[3] lay stress on the importance of an accurate study of the relative cardiac dullness in diagnosis, prognosis, and treatment. They compute the surface area of the heart by Potain's formula, taking as the vertical diameter the distance from the upper border of liver dulness to the top of the cardiac dulness, and as the horizontal diameter the line from the cardiac-hepatic angle to the apex. The product of these two diameters, measured in centimeters is multiplied by the constant .83. They studied thirty-six cases of cardiac disease in children. Two cases were congenital cardiac disease, and showed a formula a little above normal. (The type of lesion is not specified.) Two cases of adherent pericardium showed little or no increase. Twelve cases were acute endo- or pericarditis. From the acute cases they conclude (1) that increase in the precordial dulness may appear before the signs of endo-pericarditis; (2) The increase with acute endocarditis is very marked; (3) The increase is still more important with pericarditis. Their remaining twenty cases were chronic. Compensated mitral insufficiency showed only a slightly increased area, but the onset of an acute process is quickly manifested by a marked and notable increase.

Friberger[4] has made an interesting study of cardiac arrhythmia in healthy children. His observation comprise three hundred and twenty-one children from five to fourteen years of age. Complete histories were taken and physical examinations made. He found a perfectly regular pulse in none of the children. He divided the cases into three groups:

(a) Cases with slight arrhythmia..37.4 per cent.
(b) Cases with mild arrhythmia...50.4 per cent.
(c) Cases with severe arrhythmia..12.2 per cent.

Various types of irregularity were encountered. In most of the cases there was an alternation of long and short pulse. There was at times progressive increase for a number of beats, then a decrease. In other cases there was a sudden retardation at regular intervals, followed by a gradual increase in rapidity. Auricular extra-systole was seen, but real ventricular extrasystole, and auriculo-ventricular heart-block were not observed. There was an evident relation of the arrhythmia to the respiratory variations seen in children. Friberger holds that in children otherwise normal, irregularity of the pulse does not mean that there is any heart lesion.

Mackenzie[5] also lays stress on the importance of recognizing as normal irregularity of the pulse. He calls the type of irregularity characterized by the varying length of the pauses between the second and first sounds, the normal youthful type. He has never found this type associated with the true heart failure. Mackenzie further points out that the presence of heart murmurs in the young should not be taken to mean that there is any cardiac lesion. Where there is an organic lesion in the young, the signs of myocardial weakness are invariably present. Subjective symptoms are of prime importance, in recognizing cardiac weakness.

Turnbull[6] points out that the appearance of extrasystoles, if they have not previously been present, are strongly suggestive of myocardial changes in children. Increasing cardiac instability, makes active progessive myocardial change very probable, with correspondingly serious prognosis.

Poynton[7], in a paper on "Some of the Rarer Occurrences in the Rheumatism of Childhood," mentions tachycardia as a comparatively rare occurrence. He believes it to be commoner when the myocardium is affected out of proportion to the valves.

Important studies have been published recently on the pathological histology of the myocardium after diphtheria. Tanaka[8] examined the hearts of fifteen children dying of diphtheria. He found in all cases myocardial regeneration, consisting in fatty degeneration, or waxy-like degeneration with loss of cross striations and partial or complete loss of nuclear staining. He attributes the acute cardiac weakness entirely to these myocardial changes. He found no special involvement of the auriculo-ventricular bundle, and believes that changes in the bundle of His cannot be regarded as the cause of death in these cases.

True heart-block has been recently reported in a number of fatal cases of diphtheria. Magnus-Alsleben[9] has reported a case of complete heart block in a child of 8 years, dying of diphtheria, in which the bundle of His showed a severe parenchymatous degeneration. Fleming and Kennedy's[10] case showed on the sixth day of diphtheria a marked variation in the pulse rate, from 40 to 88 per minute. On the eighth day there was evidence of cardiac dilatation. Death occurred on the ninth day. Tracing showed the auricles and ventricles contracting at different rates. The auriculo-ventricular node and the first part of the bundle showed an acute inflammatory condition. The myocardium of both auricles and ventricles showed degeneration. The vagi showed no changes.

Rohmer[11] has also studied heart block appearing several days before death in diphtheria. The clinical studies were supplemented by observations with the electrocardiograph. He found that even in cases showing heart-block, the His bundle was only very slightly affected. Waxy degeneration with interstitial changes was found in scattered areas, but never involving more than half the diameter of the bundle. On the other hand the myocardium in general gave very marked evidence of fatty degeneration. Injection of large doses of diphtheria toxin into rabbits failed to produce any lesion of the bun-

dle of His. Rohmer believes that diphtheria toxin has no selective action for the tissue of the His bundle, but it may so affect the functioning power of the bundle that heart-block may be produced.

Numerous cases of heart block in early life aside from diphtheria, have been published recently. Galloway and Fenton[12] have reported a case of typical Stokes-Adams disease in a boy of 18. The pulse rate was 32 to 40 per minute, and he had repeated fainting attacks. The auricular-ventricular rhythm was usually 2 to 1, but occasionally 1 to 1.

Armstrong and Mönkeburg's[13] case was in a boy 5 years old. Tracings from the jugular vein and radial artery showed no relation between the auricular and ventricular systoles. The pulse was 40 to 50 per minute. The boy died in an epileptiform attack. Autopsy showed a lymphangio-endothelioma of the auriculo-ventricular node.

Cleveland's[14] case was in a boy of 15, who had attacks of unconsciousness without convulsions and a pulse rate of about 30 per minute. Autopsy showed hypertrophy of the left ventricle but no valvular disease. There was no microscopic examination of the auriculo-ventricular node or bundle.

Fulton, Judson and Norris[15] report three cases of heart block in the same family, the father, aged 41, a daughter, aged 20, and an infant of 22 months. They accept as the most reasonable explanation of this rare occurrence a probable congenital abnormality in the bundle of His, or of its blood supply.

Gill[16] reports a case of congenital heart block. The patient was 3 years old, small for her age, but fairly well nourished. The pulse rate and respiration rate were both 50 per minute, and were usually coincident. Occasionally there would be a deep sighing inspiration followed by a longer pause, but during this pause the heart would continue to beat as before. There were never any epileptiform seizures. The tracings of the jugulars were unsatisfactory. Death occurred suddenly, and no postmortem was allowed.

Hecht[17] reports two cases illustrating the occurrence of both functional and organic heart block in childhood, and the distinction between them. The organic case occurred in a child of three after diphtheria. There was extreme bradycardia. The tracing showed a block, and atropine had no effect. The functional case was also in a child of three, occurring after measles. The tracing also showed a block, but under atropine the bradycardia disappeared, and eight days later it disappeared spontaneously.

Pisek and Coffin[18] have found the polygraph of undoubted diagnostic aid in the cardiac conditions of childhood, used in connection with the ordinary methods of treatment. They have found it useful in indicating the approach of digitalis heart-block, by showing irregularity of the cardiac action under the use of this drug. They coincide with the other writers in finding respiratory arrhythmia very frequent in childhood, but do not regard it as always physiological, believing that it may be an indication of myocardial change.

Hoobler[19] has contributed an interesting addition to our knowledge of blood pressure readings in childhood. He calls attention to the value of his method of indicating both systolic and diastolic blood-pressures in childhood. The details of his instrument can be found in his first publication on the subject[20]. He has found that his instrument compared very closely in efficiency with the Erlanger sphygmomanometer, that it indicates both pressures automatically and visibly, that it eliminates the element due to the personal equation, and that it is of special value in children, since it permits the use of the leg when the arm is too small.

Leitao[21] has measured the blood pressure in two hundred healthy children from one to three years of age, 70 per cent. being in the first year. He found the blood pressure normally low in infancy, averaging about 70 mm. in the first six months of life, going up very slowly to the fifth year. The pulse pressure is relatively higher than in adults, and increases progressively.

Several writers have contributed to our knowledge of the prognosis of valvular disease of the heart in early life. Heinrich[22] comments on the more favorable prognosis which the course of time has brought. He mentions that Benfy has reported five cases in which the patients lived to be 17, 20, 27, 42 and 69 years old, that Cassel has reported three cases of complete recovery from mitral insufficiency in children, and quotes several other cases of recovery.

Gilbert[23] has studied 197 cases of endocarditis admitted to the Massachusetts General Hospital from January 1, 1901 to January 1, 1913, with interesting statistics as to the distribution of the lesions, and of the etiology. The result in the cases discharged with valvular lesions have been better in the later period, when continued treatment including careful supervision of the entire life of the child was carried on after the patients were discharged from the hospital. Of 42 cases discharged and treated in this way, 35 or 83 per cent. were compensated at the time of writing. He believes the continued treatment and careful supervision has much to do with the good results noted thus far. He notes the liability to relapse of acute endocarditis, and believes that endocarditis should be considered as acute over a much larger period than has been the custom. He believes that treatment should be continued until adolescence is passed.

Dunn[24] reports on 283 cases of acquired cardiac disease admitted to the Children's Hospital previous to 1903, of which 180 were followed after their discharge to the date of writing. The mortality in the first cardiac attack was 20 per cent. The mortality in those discharged, followed for at least ten years, was 51 per cent.

The final mortality of all the cases, including those dying in the hospital, and those dying later, was 63 per cent. Of the 180 patients discharged, 88 were alive after at least ten years. 140 cases died before the age of 14, most of them in a recurrent acute attack, and only seven cases have died after passing the age of puberty. The most notable point as bearing on prognosis was the remarkable freedom from disability of the survivors, 77 out of 88 being apparently fully compensated at the time of writing. Dunn believes that the prognosis is more favorable for adult life, the earlier in childhood the lesion is acquired, provided that the patient escapes the great danger of recurrent acute attacks which persists throughout childhood. No especial care or supervision was exercised in this series. We believe that if such a treatment as that described by Gilbert had been carried out during the remaining years of childhood, it is very possible that the very great subsequent mortality during childhood might have been reduced.

Moon[25] points out that the diagnosis of cardiac disease in childhood is made easier by the fact that the lesions are the results of inflammation, and not degeneration, and that it is unnecessary to consider all those degenerative changes comprehended under the term arteriosclerosis. He calls attention to the fact that chronic cardiac disease in children tends to produce a condition of malnutrition and wasting, which should lead us to suspect the heart. In the matter of treatment he lays stress on the importance of guarding the child from a fresh attack of rheumatic fever, and on the importance of allowing exercise in moderation to compensated cases.

Cockayne[26] investigated the possible influence of the salicylates on the occurrence of cardiac lesions in chorea. Of 780 cases, 355 patients were given salicylates, and 425 received other treatment. If the drug had no effect, the cases showing cardiac change should be in the proportion of thirty-nine untreated to thirty-two treated with salicylates. The actual proportion shown in 77 cases which developed signs of cardiac involvement was thirty-nine in the untreated to thirty-eight in the treated. The figures are so close that the disparity can have no significance, and Cockayne concludes that the salicylates appear to have no action influencing cardiac involvement.

Reports of Societies.

NORFOLK DISTRICT MEDICAL SOCIETY.

MEETING OF OCT. 28, 1913, HELD IN ROXBURY, MASS. BRADFORD KENT, M.D., SECRETARY.

DR. WILLIAM W. HOWELL read a paper entitled,

SUGGESTIVE TREATMENT IN DISEASES OF CHILDREN.*

DISCUSSION.

DR. E. W. TAYLOR: It is gratifying to those of us who are particularly interested in the nervous system that Dr. Howell has taken up the subject of suggestive treatment. The evidence is increasing that this subject is no longer to be regarded as a special field in medicine, but that practitioners of whatsoever sort are coming to see its importance and universal application. As applied to children, the whole matter of psychotherapy is of peculiar significance. The feeling is growing that even young children are peculiarly susceptible to mental influences, and it naturally follows that such influence should be carefully directed and applied with the same scientific precision as is used in other departments of therapeutics. It is clear that one of the most important subjects of the immediate future is a more painstaking study of the child's mind in the light of the accurate knowledge which is rapidly accumulating, and to this Dr. Howell has drawn our attention in his paper. There are many methods of psychotherapeutic procedure, some of which in my judgment are much more useful than others. Hypnotism, one of the cruder and earlier methods, is no longer used to any extent as

* See page 230 for full text of this paper.

a therapeutic measure, owing essentially to the fact that it relieves symptoms but fails to strike at the root of the difficulty, much as morphine may relieve pain but masks rather than reveals underlying causes. Suggestion in the sense in which Dr. Howell has applied it is in a measure open to the same objection; though less crude than hypnotism, it still fails in many cases to reach the source of the difficulty. I am inclined also to think that Dr. Howell's method of giving bad tasting medicine or applying similar methods to influence the mental state of the child is on the whole undesirable, although I can easily see that in certain cases no other might be available. It is probable that if sufficient time were given, it would be possible in many cases, even in comparatively young children, to use less drastic means with equal effect, and to explain the significance of symptoms rather than to attempt their removal without such explanation. This leads to the most significant advance in psychotherapy of the past decade, which goes under the general name of psychoanalysis and is particularly associated with the name of Freud. Leaving out of consideration entirely the question of sex, which in certain quarters seems to have brought the method into disrepute, we should certainly see in the underlying principle one of the most significant steps in practical psychology which has ever been made. I refer to the sincere attempt to analyze in the light of existing symptoms the conditions which have led up to those symptoms. Whether these conditions are sexual or not is a matter of relatively small importance provided the principle be distinctly understood that such an analysis is the first sincere attempt to get at causes, and that thereby psychotherapy has been established as a scientific procedure precisely in the sense that the study of etiology in bodily disorders is a scientific procedure. As is now generally known, such psychoanalysis has been applied to children as well as to adults. Its difficulties are manifest, but that it represents an attempt in the right direction should no longer be questioned. We are certainly indebted to Dr. Howell for having brought this subject to our attention, and in advocating an analytic method, I should not wish to be regarded as deprecating cruder procedures which it must be freely admitted may often accomplish most excellent results, as in fact Dr. Howell's cases have demonstrated.

DR. C. D. KNOWLTON: Dr. Howell always writes a good paper. It is with much pleasure that I have followed his excursion into suggestive therapeutics from the standpoint of the specialist in diseases of children. It is also a pleasure to hear Dr. Taylor's clear and forceful presentation of the subject, coming as it does from his ripe experience as a neurologist. What have I, as a general practitioner, to say? One of our chief functions is to continually scrutinize the ground, north, east, south and west to be sure that our specialist friends are not putting one over on us. Tonight I believe we have listened to the real thing and to further support this belief let me quote you a few sentences from recent authors. Chapin and Piesek say that often a good part of a physician's success in handling children is due to his knowledge and interest in their mental processes. He learns to take advantage of their susceptibility to conviction, to suggestion, or of their pride, and control is thus easily acquired. Time spent in studying the mental attributes of a seemingly incorrigible patient is well spent, for almost without exception the maturer mind conquers by persistence, tempered with kind indifference. Pfaundler and Schlossman say that in the care and treatment of a child at any age the psychical effect is of the greatest importance. The inner life of the child is not sufficiently understood by nurses and doctors. To be successful we must carry out all painless procedures without producing resistance on the part of the child. We do this by a friendly manner, diverting attention and encouragement, thereby causing the child to become trustful and docile. Active suggestion requires positive exhortation whereby a child's attention is fixed upon the doctor; impressive manipulation as medicaments, electrical current, massage, passive and active exercise. Psychic influence is in varied methods of treatment—sojourn in the country, baths, sanatoria. Association with other children of the same age acts as above by producing (a) sense of new impressions (b) change in routine (c) improvement in temper (d) new impulses in the will (e) change in the tone of all the functions. The preliminary conditions of an adequate course of psychic treatment are (1) Protect the patient against an unhygienic habit of life—poor food, disturbed sleep, overfatigue, etc. (2) Suitable conditions of mental hygiene—avoid irritating and depressing surroundings and no contact with persons who are themselves of an unhealthy, ill-balanced mental disposition. (3) Requisite relation to the physician himself for the time being—authority absolute in all severe cases superceding, by delegation, that of the most responsible of the patient's family or friends. Hence the position of the psychotherapeutist becomes one of trust, entailing obligations that are as deep and sacred as those involved in any relation in life.

DR. M. H. A. EVANS: Dr. Taylor has spoken of the importance of the early life of the child. I believe this point cannot be too strongly emphasized. It is during the first five or six years of life that we can accomplish most toward the prevention of nervous disorders in later life. Leaving a silent and almost absolute calm the newborn is projected into a confusion of movement, sounds and light. The five senses are alert and during the waking moments the brain is undoubtedly subjected to a very great strain as it attempts to sort and classify the many recorded impressions. As soon as any single impression is recognized in its relation to anything else it represents an association of ideas. Think how early this process begins: Every smallest part of the infant experience is important then for it is upon the experience then acquired that the child depends for its thought in the future. Every new idea must be reconciled to these first ideas. If we furnish unhealthful material or faulty data to be absorbed and incorporated in the experience of a child, that child must at some time in after life either laboriously dissect and then reconstruct the data in accordance with the truth, or go through life forming false conclusions and exhibiting inconsistent and unhealthy mental reactions. We should be exceedingly careful that we do not introduce false ideas into the rapidly filling mind. We should present only accurate and clearly defined data. We should, above everything else, offer wholesome material for its consumption. Do not permit a child to hear statements that are not intended to be received and acted upon. "She is a delicate child; never was very strong," may well be expected to result in an unqualified acceptance

of this condition, and who is to question the right of this child to grow to adult life believing that she is a delicate person and that she is not strong. Let us teach children to think of themselves as strong and well and this attitude may be expected to persist. They will build their thoughts on this groundwork and develop a tendency to be well which may help us out as doctors many times when we despair of our physic.

DR. HAROLD: In closing the discussion I wish to thank Dr. Taylor for emphasizing the importance of the method by analysis. However important it may be in treating adults it is not applicable to young children for they are not able to follow the analyses of a complicated psychic problem and in most cases they have forgotten the original trauma, physical or psychic, and consequently their troubles do not lend themselves to analysis. Dr. Taylor said the suggestive method as used was more or less a punishment. In fracture the children do not regard it as such, if properly used. I have had children take bad tasting medicine or ask for faradic current, believing it was to cure them, at the same time dreading the drug or electricity. I believe the suggestive method is the only practical method with children.

MIDDLESEX EAST DISTRICT MEDICAL SOCIETY.

The regular meeting of the Middlesex East District Medical Society was held at the American House, Boston, Dec. 17, 1913, thirty-one members being present. A. E. Small, M.D., Secretary. The paper of the evening was read by Dr. John L. Morse of Boston, on

INFANT FEEDING AND DIGESTIVE DISTURBANCES.

Abstract: The importance of breast feeding was emphasized, calling to mind that if only one or two breast feedings were possible daily the infant would handle the bottle all the better.

The only substitute for breast feeding is some modification of cow's milk. There is no reason for giving any proprietary food as there is nothing in any of them which cannot be put into the milk at home or in the laboratory. If a proprietary food agrees and modified milk does not, it simply means that the doctor has not thought of the right thing to use; he has not made the food fit the baby. We must have a clean milk to start with. In the fall we see certain cases of disturbed digestion because the cows have had too much green corn or too many apples. In the winter the freezing of milk alters the emulsion of the fat and produces a disturbance the cause of which is not often recognized.

In prescribing modified milk (which simply means changing cow's milk) we think of the food elements we want and the proportions. This leads us to percentage feeding, which is merely calculating accurately what we want to give. There is often difficulty in deciding what we want to start on. Tables, which are formed on the basis of experience for well babies, are given to help us tell what the baby probably can take. After the first mixture the feeding ought to be based on definite indications as shown by the character of the stools, presence of gas, vomiting, etc. Taking in detail some of the indications showing an excess or deficiency of one of the food elements, we will consider first, fat. If there is too little fat there is apt not to be any gain in weight. If too much, there is vomiting, with an odor to the vomitus of fatty acids, infant may lose its appetite, have gas, or abnormal stools, one of three types usually. First, oily type.—if the stool is rubbed on paper and the paper let dry, it has the appearance of oiled paper; second, the presence of small, soft curds; third, the soap stool, dry, light colored and crumbly. The sugars are the sources of energy and not tissue builders. The fat and sugar can be used to a certain extent interchangeably, but the fat holds liquids in the cells better. Milk sugar is the normal sugar and because it is slowly broken up it remains a source of energy for a long time. Maltose is much emphasized at present. Pure maltose is a laboratory product and too expensive to use. What is used is a mixture of dextrine and maltose, no two mixtures being alike. Dextrose is the sugar of the blood and as such is immediately available, no energy being wasted in changing it to another form of sugar nor in storing it as glycogen. A feeble baby with no glycogen in its liver or muscles needs all its energy for digesting its food, so that the maltose dextrine preparations, which are the most easily convertible to dextrose are the best. The ordinary baby has plenty of glycogen or readily available energy and he needs a sugar more slowly broken up and one which will not flood the system. Thus for him lactose is the best sugar. Cane sugar lies in between the two for availability, so has no necessity except for cheapness. A well baby will take any kind of sugar but a sick one is another proposition.

The proteids are the tissue builders and if not high enough in proportion the infant will starve to death. Casein and whey are the two forms of proteid. Proteid indigestion is shown by the presence of gas and stools, either dark brown watery with a foul musty odor, or with large hard curds. If casein is not easily digested we can do various things to prevent large curds from forming. First, we may dilute the mixture; second, may use whey; third, may boil the milk; fourth, may add cereal water; fifth, may add an alkali; or, sixth, may add sodium citrate.

A breast-fed baby gets no starch, but it has a pancreatic starch ferment present at birth. Clinically, it is wiser not to give starch before the third month except for some definite purpose. The main object is for the colloidal action in preventing large casein curds. Three-quarters of one per cent. has as much effect as a larger amount.

With regard to pasteurizing milk, there is no theoretical or clinical evidence to show that it hurts the milk as a food. Nevertheless statistics for the past two years have shown a steady increase in the percentage of cases of scurvy coincident with the increase in the use of pasteurized milk, which is at least suggestive.

Fermentation of milk sugar is shown by acid vomitus, stools which are loose, green, frothy and irritating to the buttocks. In treatment, cut down the quantity of milk sugar and also the fat, as it is secondarily involved. Finkelstein's eiweiss milch fits the case perfectly but is no better than skim milk and barley water boiled. Then begin and work back. Here maltrose dextrine is valuable and fills a place no other sugar will.

Disturbance from starch gives fermentation, hard, dry brown stools, easy to recognize with tr. iodine.

Do not mistake it and mucus, which is always present in stools following the use of castor oil. In infectious diarrheas the bacteria penetrate the walls, get into the circulation and cause toxic substances. In all of them there are small dejections with mucus and blood due to the action of the bacteria in the walls of the intestine. There may be a variety of organisms which necessitate different lines of treatment. The dysentery bacillus when grown on carbohydrate food does not form toxic substances, hence give carbohydrate food in the treatment. The use of frequent doses of castor oil and starvation is the worst possible treatment, as all the intestinal secretions are proteid in nature. The gas bacillus, on the contrary, thrives on sugars and starches; so give a proteid diet. Here buttermilk is also useful, as the lactic acid bacillus is antagonistic to the gas bacillus. The milk test often does not work for the amateur, so that he practically has to try the influence of one or the other diets on the infant, and if it grows worse, switch. Usually one infection or the other prevails during a given season.

After a brief discussion the meeting adjourned.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

STATED MEETING, WEDNESDAY, NOVEMBER 5, 1913, AT 8 P. M.

The President, DR. JAMES C. WILSON, in the chair.

THE RESULTS OF THE TREATMENT OF POLIOMYELITIS BY OPERATIVE MEASURES. ILLUSTRATED BY CASE.

DR. G. G. DAVIS: In recent years operative surgery has opened a new field in the treatment of infantile paralysis or acute poliomyelitis. The patient presented tonight is an illustration of what can be done for this class of cases. I strongly suspect that as we become better informed as to what can be achieved by operative procedures in these cases they will be earlier resorted to than at present is considered advisable. The patient, a boy of thirteen, was paralyzed at the age of one year. The parts involved were the lower part of the trunk and left lower extremity. The back was partly affected, also the region of the hip and almost all of the muscles of the thigh with the exception of the biceps or external hamstring and one or two of the muscles moving the foot. As he grew older a knock-knee developed. He wore braces for seven years. The first operation was an osteotomy of the femur, done in December, 1910. In the following March an arthrodesis was done to fix the flail foot. The biceps femoris tendon was loosened from its attachment on the fibula and inserted into the top of the patella; and while the foot was strongly inverted the fascia lata was slit in a longitudinal direction and sewn fast with silk sutures behind the greater trochanter. He wore a brace for a while until the various operative procedures had well healed, and then discarded it, and his walking has improved ever since. This operation (devised by the writer) was performed with silk buried suture, but chromicized catgut is now used.

The fixation of the ankle eliminated movement at that joint and also to a considerable extent of the joint between the astragalus and os-calcis. The mediotarsal joint, in front of the ankle, not being interfered with, allowed the anterior part of the foot to droop somewhat, but not enough to allow the toes to catch in walking. The lateral movement of the foot was also eliminated to a sufficient extent to remedy the tendency to valgus. The transplanted biceps muscle can be seen to contract perfectly and holds the knee back in walking so that it does not tend to collapse when weight is put upon it. The holding of the thigh in a position of internal rotation by fastening the fascia lata to the posterior edge of the greater trochanter corrected the outward turning of the foot in walking.

DISCUSSION.

DR. J. TORRANCE RUGH: I do not believe that a case of greater orthopedic importance could have been presented to us. Dr. Davis has shown some of the advanced work with this most troublesome class of cases and has obtained about as good results as one can possibly hope for. In Italy I saw Professor Putti do an operation which to my mind takes the place of arthrodesis for the ankle joint especially in cases of this type. He separates the anterior tendons from the muscles high up on the leg. Then a hole is drilled through the tibia, and the tendon ends are drawn through this hole and fastened subperitoneally in front of the tibia, some of the tendons being passed through from one side and others from the other side. He thus shortens the tendons and leaves purely tendonous structure between attachment and insertion and the tendon acts as a ligament and will not stretch. It is the badly degenerated muscle tissue which stretches. If there is sufficient contractive power on the part of the posterior tendons the anterior ones can be shortened and the foot maintained in the proper position, or if there are live muscles anteriorly, the posterior tendons are shortened in the same manner and the necessity of an arthrodesis is avoided. The demonstration given in Dr. Davis' case in the transferred power of the hamstring tendons is one of the best examples of what can be done in these cases. Operative measures, of course, should not be undertaken until it is certain that complete, or all possible regeneration, has taken place, and that there is no possibility of return of power in the muscles. Not until about six years after the onset of the paralysis should operative measures be instituted.

DR. WILLIAM J. TAYLOR: I can only congratulate Dr. Davis upon the wonderfully good results obtained in the use of this modern method of treating these otherwise hopeless cripples.

DR. CHARLES K. MILLS: I do not think that in my rather considerable experience with cases of poliomyelitis treated by older methods, and somewhat different forms of operation, I have ever seen a case in which the results were so very good.

DR. DAVIS (closing): My desire in bringing before you this case was to exhibit a case which was practical, a badly crippled patient, one who had been wearing apparatus ad nauseam, and to show that if one is willing to take the time and trouble, a great deal can be done for such patients. Often they can be enabled to walk entirely without apparatus, as in this case. This special boy was selected because he happened to combine in his own

person paralysis of three different parts of the body, the foot, the knee and the hip.

RESEARCH STUDIES IN PSORIASIS.

(Lantern Demonstration.)

By DR. JAY F. SCHAMBERG and DR. A. I. RINGER, DR. G. W. RAIZISS and DR. JOHN A. KOLMER (by invitation).

DR. SCHAMBERG: A careful study was made of the protein metabolism of eight psoriasis patients and the following observations noted:

1. That on a given protein diet a psoriatic subject eliminates less nitrogen in the urine than does a normal individual on a corresponding diet. The urinary nitrogen in some instances reached a level lower than has ever been recorded.

2. Patients suffering from psoriasis exhibit a remarkable retention of nitrogen. This retention appears to be proportional, in a general way, to the extent and severity of the eruption.

3. The nitrogen is retained to a greater degree than has been observed in connection with any other condition, and is retained with great ease on a diet low in nitrogen and insufficient in caloric value, and one upon which a normal individual would fail to maintain equilibrium.

4. Experiments with urea feedings show conclusively that the nitrogen retention cannot be attributed to any disturbance in the eliminative capacity of the kidneys.

5. Patients with extensive psoriasis may lose very large amounts of nitrogen in the exfoliated scales, which consist of almost pure protein.

6. The retention of nitrogen in most of our cases is greater than can be accounted for by the protein lost in the scales, and it may persist even after scaling has ceased and the eruption has virtually disappeared.

7. A low nitrogen diet has a most favorable influence upon the eruption of psoriasis, particularly when the latter is extensive. Making all reservation suggested by scientific caution, we feel that there can be no doubt that severe cases of psoriasis improve under such a diet almost to the point of disappearance of the eruption.

8. Conversely, a high nitrogen diet exhibits an unfavorable influence on psoriasis, commonly causing an extension of the eruption.

9. Whether a high nitrogen diet can stimulate an outbreak of psoriasis in a psoriatic subject, who is at the time free of the eruption, has not yet been determined.

10. The great proliferation and exfoliation of cells by the skin in psoriasis demand a large supply of protein, which can only be procured from the lymph and blood streams. This protein supply may be derived from the ingested food, and a possibility exists that the great demand of the diseased skin for protein may also be satisfied by the protein reserve in muscle tissue, which thus may become depleted and later require restoration. This would explain the ready and persistent retention of nitrogen in our cases.

11. A protracted low protein diet may diminish the proliferative activity of the skin by diminishing the supply of the principal building material, namely, protein. On the other hand, a high protein diet may stimulate the proliferative activity of the cells by furnishing an abundant supply of the necessary protein.

12. We deem it premature at the present stage of our research studies to commit ourselves to an hypothesis as to the primary cause of psoriasis. Our investigations are being continued and extended in various directions.

TRANSACTIONS OF THE AMERICAN SOCIETY FOR THE PROMOTION OF CLINICAL RESEARCH, WASHINGTON, D. C.

MAY 5, 1913.

(*Concluded from page* 209.)

EXPERIMENTAL CARDIAC HYPERTROPHY STUDIED BY MEANS OF THE X-RAY.

DR. HENRY A. CHRISTIAN, Boston:

Owing to marked variations that occur in the weight of rabbits and the size of their hearts, it is not easy to determine whether or not in a given rabbit hypertrophy and dilatation of the heart has been produced. In following cardiac lesions produced by intravenous injections of adrenalin and spartein, it was found that though very frequently myocardial lesions were produced which led to cardiac hypertrophy and dilatation this was not a constant result, and it was of interest to know whether at a given stage of the experiment changes in heart size had been produced. It was found that by means of the x-ray variations in the size of the heart could be easily determined. In a series of animals studied by this means, it was found that very considerable increases in the weight of the animal might occur without there being marked changes in the size of the heart. Following injections of adrenalin and spartein very considerable increases in the size of the heart were produced. It was also found that enlargement of the heart continued for a long period after injections of these drugs had ceased, and that in some of these hearts actually less pathological change other than hypertrophy of muscle fibres, was found in the myocardium than in animals killed at a shorter time after the doses of spartein and adrenalin, though the hearts of the latter did not show so great enlargement.

DISCUSSION.

DR. S. J. MELTZER, New York: I have no doubt Dr. Christian is familiar with the work of Gruber of our laboratory, who has made very many estimations of the comparative size of the heart and the animal; the relation is rather constant, but he has found that the estimates must be made after the removal of the contents of the abdomen. So it would seem that in making measurements of the heart by x-ray much would depend on the contents of the abdomen and the position of the diaphragm.

Discussion closed.

DR. H. A. CHRISTIAN, Boston: We are interested in getting the average heart weight as compared with the body weight. I am aware of Gruber's work, but our efforts were directed toward estimating the heart weight with the heart *in situ*.

KIDNEY FATIGUE WITH DIURETICS IN EXPERIMENTAL NEPHRITIS.

DR. HERMAN O. MOSENTHAL, New York:

Researches conducted by Schlayer[1] on human nephritis showed that diuretics used in too large doses, will in certain cases suppress urinary secretion rather than augment it, that is to say, they will cause kidney fatigue. In other instances sodium chloride effected the same results. It was in order to elucidate some of these phenomena that the following experiments were undertaken.

Rabbits anesthetized by the subcutaneous injection of urethane, were given three successive intravenous injections of 5 ccm. of 5% solution of sodium chloride, followed by three successive intravenous injections of 2 ccm. of 5% caffeine sodium benzoate solution. The diuresis was measured by collecting the urine at ten-minute intervals; the reaction of the intrarenal vessels by an oncometer applied to the left kidney. The experiments were first performed on normal rabbits and subsequently on those in which experimental nephritis had been produced by potassium chromate and uranium acetate. The latter were subjected to the tests from a few hours up to several days after the poisons had been administered so that the progress from one phase to another of the nephritis could be satisfactorily studied. The anatomical difference between the two forms of nephritis is very slight. Both poisons damage the cells of the convoluted tubules very markedly and the glomeruli only slightly.

Normal rabbits showed no signs of diminished renal function after the series of three salt injections but a very marked fatigue after the twice-repeated use of caffeine. This fatigue manifested itself in the inhibition of the diuresis as well as in the diminished dilatation of the kidney vessels. Salt injections following the caffeine series again produced diuresis, thus showing that the mechanism of salt and caffeine diuresis is not by any means identical.

RESULTS WITH CHROMATE NEPHRITIS.

In the earlier stages of chromate nephritis salt produces a diuresis and increases the dilatation of the renal vessels, much as in the normal kidney. Caffeine, however, very rapidly causes kidney fatigue, much more rapidly than in the normal kidney, so that in some cases anuria results and the kidney vessels contract instead of dilating. Furthermore, the after-effects of the caffeine are seen when salt is subsequently administered intravenously and no longer calls forth a diuresis as it did in the normal kidney after the use of caffeine. The demands put upon this form of nephritic kidney by the sodium chloride must be responisble for the fatigue evinced by the kidney after caffeine, for if the caffeine be preceded by only one dose of sodium chloride instead of several, the evidences of fatigue do not appear.

In this connection an interesting point is observed in the final stages of both chromate and uranium nephritis, when anuria or very much diminished kidney secretion has been produced. In these instances it is found that although salt and caffeine no longer cause diuresis, the kidney vessels are still dilated. These and other similar results obtained in the course of these experiments lead to the conclusion that the quantity of urine does not constantly parallel the volume of blood flowing through the kidney, as many physiologists would have us believe, but that diuresis may occur without dilatation of the renal vessels and vice versa.

[1] Verhandl. d. Cong. f. innere Medizin, 1912, 501.

RESULTS WITH URANIUM NEPHRITIS.

In the initial periods of uranium nephritis the effects of sodium chloride are approximately the same as those seen in the normal animals. Caffeine causes no decrease in diuresis; however, the dilatation of the blood vessels is markedly diminished, which may be considered a sign of fatigue. This is another example of the lack of parallelism between dilatation of the renal vessels and diuresis. In the terminal stages of this as well as of the chromate type the blood vessels of the kidneys are still dilated but no urine is secreted. In this form of poisoning a type of functional reaction may be seen intermediate between the initial and terminal periods, *i.e.* taking the degree of poisoning as a guide. Schlayer has designated this as the "Zwischenstadium," intermediate stage. It is characterized in this series of experiments by a reaction which is different from that previously seen. The control period shows a kidney putting out an approximately normal amount of salt and water. The injection of sodium chloride results in a rise of the oncometer lever (blood vessel dilatation) but no diuresis. Caffeine, on the other hand, produces an enormous diuresis and in some cases an enormous dilatation of the kidney vessels.

Thus there are produced two diametrically opposed conditions. In the one case salt results in a good response on the part of the kidney, and caffeine in marked kidney fatigue (chromate poisoning), in the other, salt produces no diuresis and caffeine an enormous one (intermediate stage of uranium poisoning). Yet the pathological conditions of these kidneys are very similar and the final stages in both forms of poisoning the same, namely a total lack of response to both salt and caffeine.

Both of these conditions may be seen in human nephritis: suppression of urine by diuretics (as in the chromate type), lack of diuresis after administration of salt (as in the uranium type), sometimes to be dispelled by the exhibition of small doses of diuretics of the caffeine group.

A careful study of cause and effect along these lines may in the future enable us to obtain diuresis in many cases of nephritis where the blind pushing of drugs has no effect.

DISCUSSION.

DR. JOS. L. MILLER, Chicago: Were the effects of caffeine transitory or permanent?

DR. S. J. MELTZER, New York. Was urethane used in all of the cases? No notice appears to have been taken of the fact that urethane renders the kidney permeable unless it is used with adrenalin.

Discussion closed.

DR. H. O. MOSENTHAL, New York: It is difficult to say whether the effects of caffeine are permanent or not; in some cases caffeine would later produce some effect, but in nephritis caused by uranium or chromate the effects of the caffeine were permanent.

PERCUSSION OF THE PARAVERTEBRAL REGION ON THE AFFECTED SIDE IN THE DIFFERENTIATION OF PNEUMONIA AND PLEURISY WITH EFFUSION.

DR. FREDERICK T. LORD, Boston:

It is not generally recognized, although already noted, that in croupous pneumonia affecting the

lower lobes and uncomplicated by an effusion the dullness on the affected side is usually less marked in the paravertebral region than over other parts of the chest.

Among a large number of cases with pulmonary and pleural disease observed during the past year at the Massachusetts General Hospital were eighteen of croupous pneumonia affecting the lower lobes with the usual signs of consolidation and without evidence of pleural effusion. In sixteen of these cases a zone of relative resonance about two fingers' breadth in width could be demonstrated in the paravertebral region on the affected side. In one of the sixteen coincident with the development during convalescence of signs suggestive of pleural effusion but without displacement of the heart or Grocco's triangle the paravertebral resonance gave place to dullness and exploratory puncture showed empyema. In two of the eighteen cases of apparently uncomplicated lobar pneumonia affecting the lower lobes the paravertebral region on the affected side was dull, thus forming an exception to the findings in the other sixteen cases. In one of the two a crisis on the sixth day, rapid resolution and speedy convalescence left us in doubt as to the meaning of the paravertebral dullness. In the other case there were signs at the left base of consolidation over an area about the size of the palm with dullness reaching to the spine but at autopsy croupous pneumonia of the left lower lobe without an effusion was found.

The strip of relative paravertebral resonance on the affected side has seemed obvious only in the presence of extensive croupous pneumonia and absent or doubtful with small areas of consolidation at the bases from other causes. In explanation of its presence in lobar pneumonia it may be suggested that the paravertebral region on the affected side takes its resonance from uninterrupted spinal vibrations reinforced by compensatory emphysema of the unaffected lung. The supposition that compensatory emphysema plays a part in its production finds some support in the presence of an obvious degree of relative resonance only in cases with extensive pulmonary consolidation. Free pleural effusion on the other hand distends the pleural sac and interrupts these spinal vibrations with the production of dullness on one or both sides of the spine in accordance with the size of the effusion.

The presence of a zone of relative resonance in the paravertebral region on the affected side with croupous pneumonia and dullness with pleural effusion thus appears to be of some value in the differentiation of the two conditions.

DISCUSSION.

DR. W. S. THAYER, Baltimore: I suppose Dr. Lord uses the term paravertebral in the strict sense and not only in reference to the triangular area of dullness on the opposite side.

Discussion closed.

DR. F. T. LORD, Boston: Dr. Thayer's supposition is correct, and the area of relative resonance is about two finger-breadths over the extent of the infiltration.

OXYGEN CONTENT OF THE BLOOD IN LOBAR PNEUMONIA.

DR. F. W. PEABODY, Boston:

The oxygen content of the venous blood was studied in 25 cases of lobar pneumonia. Of 17 cases which ran an uncomplicated course 15 showed at all times a normal oxygen content, while two showed a transient decrease in the oxygen. In 8 fatal cases in which the blood was studied within 12 hours of death the oxygen content showed a progressive fall, and specimens of the blood saturated with oxygen showed a progressive decrease in the oxygen capacity of the blood reaching its minimum at the time of death. A similar decrease in the oxygen content of the arterial blood and in the oxygen capacity of the blood was demonstrated in fatal pneumococcus septicemia in rabbits. Butterfield and Peabody have shown that a diminution in the oxygen capacity produced by the action of the pneumococcus on blood and hemoglobin solutions is due to a formation of methemoglobin. It seems probable that the decrease in the oxygen content of the blood in fatal cases of lobar pneumonia in man is also due to the conversion of part of the hemoglobin into methemoglobin.

DISCUSSION.

DR. R. I. COLE, New York: These observations are of great importance in that they show that the blood changes in lobar pneumonia are due to toxic substances. There are those who have regarded the changes as due to acids derived from tissue waste, the acids producing methemoglobin in the blood.

DR. R. WEIL, New York: Is the cyanosis in pneumonia due to methemoglobin or to reduced hemoglobin?

Discussion closed.

DR. F. W. PEABODY, Boston: I cannot answer Dr. Weil's question certainly, but the cyanosis is probably due to reduced hemoglobin.

IRON INFILTRATION OF THE FIXED AND WANDERING CELLS OF THE CENTRAL NERVOUS SYSTEM.

DR. D. J. MCCARTHY, Philadelphia.

The result of a series of experiments on animals were inconclusive in demonstrating a structural change in the ganglion cell as a result of long-standing venous stasis or thrombosis occurring at the time of delivery. The experiments have not yet been completed, but as far as they have been carried, an artificial infiltration of hemosiderin in the ganglion cells was made in the brain from a patient who suffered from an extensive hemorrhagic encephalitis in the cortex. The iron reaction was not demonstrated in the cortical ganglion cells in this case but was obtained in a very striking cell reaction in the plasma-like cells of the pia arachnoid and in the elastic coats of the smaller cortical arteries.

CARRIERS OF ANTERIOR POLIOMYELITIS.

DR. WM. LUCAS, BOSTON, Boston.

Report on experimental work with the virus of anterior poliomyelitis in human carriers. The workers reported a case in a child that had first attack of paralysis two years and four months before the present experiments; and a recurrent attack four months before the experiments. The nasal secretions from the case were secured and passed through a Berkefeld filter and were injected intracerebrally into monkeys with typical paralysis resulting. Two successful series were tried out and carried on to the second generation, so proving the presence of the virus in human carriers.

THE METABOLISM, PREVENTION AND SUCCESSFUL TREATMENT OF RHEUMATOID ARTHRITIS; SECOND CONTRIBUTION.

DR. RALPH PEMBERTON, Philadelphia:

Metabolic and clinical observations were made on a series of 18 cases of rheumatoid arthritis.

The metabolism was studied with respect to the nitrogen, ammonia, creatinin, depression of the freezing point, titratable acidity, chlorides and total, preformed and aethereal sulphates of the urine; also the nitrogen of the feces.

Observations were, further, made on the urea and non-coagulable nitrogen of the blood by Folin's new methods. The elimination capacity of the kidneys was studied and anaphylactic experiments were conducted to detect the passage through the bowel of heterologous proteid.

Of the 18 cases studied and treated, two had had the disease more than 18 years. All were treated by dietary measures, and no other medication, with the result that the disease was arrested in all but two, who were distinctly benefited.

In the light of later knowledge, these also could, without reasonable doubt, have been made to respond more. The restoration of function was surprising and information of interest was obtained as to the nature of the atrophic, hypertrophic and infectious varieties, etc.

Rheumatoid arthritis apparently belongs in the general category with gout and diabetes, in that there is a level of metabolic equilibrium at or below which the patient has no symptoms. Above this level, joint disturbances occur. Early cases are easily cured and it seems justifiable to say that, apart from permanent bone destruction or overgrowth, the disease can be arrested and is preventable.

A UNILATERAL TYPE OF INTERMITTENT CLAUDICATION OF THE LUMBAR REGION; WITH REMARKS ON BACKACHES OF VASCULAR ORIGIN.

DR. J. RAMSAY HUNT, New York:

A further contribution to intermittent claudication of the lumbar region. Description of two cases presenting the typical symptoms of this affection, strictly unilateral in localization and confined to the musculature of the lumbar region. In one case there was an aneurysm of the abdominal aorta.

Symptoms consist of pain, cramp-like sensations and weakness in the affected region, which occur regularly during exertion and cease immediately after a brief period of rest. These symptoms never occur in the recumbent posture or while sitting with the back supported, but always appear after muscular exertion, exactly as in intermittent claudication of the extremities, all phenomena promptly subsiding, when the muscles of the back are placed at rest.

A description of a clinical type of backache, occurring in elderly people and of vascular origin: It is characterized by weakness, stiffness and aching pain in the muscles of the lumbar region coming on after exertion and ceasing immediately after a brief period of rest. The movements of the spinal column are normal, there is no tenderness on pressure and the lumbar distress is only present after exertion, never in the recumbent posture or while sitting. In such cases the lumbar distress is even produced by forward bending movements of the spine which causes an increased activity of the muscles concerned.

The pathology of these backaches as in the more pronounced type of the lumbar intermittent claudication is an interference with the blood supply to this region through the lumbar arteries,— either from arteriosclerotic affections of the lumbar arteries themselves, or of the abdominal aorta from which they take their origin. The blood supply is sufficient so long as the muscles are at rest, but the increased demand required during activity is not forthcoming and as a consequence the symptoms of muscle ischema are the result. As the muscular activity ceases the circulation is again sufficient and the symptoms promptly subside.

The author is of the opinion that this group of ischemic backaches in the more advanced period of life is by no means a small one and that many of the stiff and painful backs at this period of life may be of vascular origin.

MIDDLESEX EAST DISTRICT MEDICAL SOCIETY.

The monthly meeting of the Middlesex East District was held as usual at the American House, Jan. 21, 1914, President Keleher presiding. A. E. Small, M.D., Secretary.

Owing to the severe storm only eleven members were present to hear an informal talk by Dr. Herbert B. Howard, Superintendent of the Peter Bent Brigham Hospital. He gave a brief history of Peter Bent Brigham and the accumulation of his fortune which was left to the people of Suffolk County. Plans of the hospital were shown, illustrating how the greatest amount of sunlight and fresh air are obtained, how the beds may be easily rolled out of doors, suspected contagious cases easily isolated and removed if they prove contagious. The unique arrangements for heating the floor of the wards, and many other features of construction and administration. The hospital has an unusually large medical and surgical staff in proportion to the number of patients, in order that the unusual and difficult case, which is the kind desired, may be adequately and thoroughly studied.

Book Reviews.

A Practical Treatise on Medical Diagnosis. By JOHN H. MUSSER, M.D., LL.D. New (sixth) edition, revised by JOHN M. MUSSER, JR., B.S., M.D. Octavo, 793 pages, with 196 engravings and 27 colored plates. Philadelphia and New York: Lea and Febiger. 1913.

The sixth edition of Musser's Practical Diagnosis has been revised by his son. This edition is somewhat more condensed than the earlier editions. For those students and general practitioners who wish a single book covering the important points of medical diagnosis this revised work should be eminently satisfactory.

THE BOSTON
Medical and Surgical Journal

THURSDAY, FEBRUARY 12, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

CHRONIC INTESTINAL STASIS.

THE subject of chronic intestinal stasis, which has been attracting so much attention of late, has received a new impetus from the recent visit to this country of Sir Arbuthnot Lane of London, whose work in this direction may fairly be described as little short of epoch-making. Lane, as is well known, holds that practically all chronic illness has its real origin in the intestines, and has repeatedly made the assertion that a long series of affections, including such grave conditions as tuberculosis, cancer, rheumatoid arthritis, and Bright's disease, are brought about by the enfeebled resistance which the tissues, poisoned as the result of intestinal putrefaction and intoxication, offer to the invasion of microbes or other sources of infection. As was pointed out by Dr. W. Van Valsah Hayes in a recent paper, it is certainly startling that a man whose life work has been almost exclusively of a surgical character should have advanced such a claim. Dr. Hayes' paper was one of three in a symposium on chronic intestinal stasis at the December meeting of the Medical Association of the Greater City of New York, in which the medical aspect of the subject was considered by him, its radiological aspect by Dr. A. Judson Quimby, and its surgical aspect by Dr. William Seaman Bainbridge. This was a noteworthy and admirable piece of "team work" on the part of these gentlemen, as the patients whose cases were described, a number of whom were present and anxious to show the excellent results which had been achieved, had had the benefit of the coöperative services of the three.

In an address delivered not long since at the North-East London Post-Graduate College, Lane gave the following definition: "By chronic intestinal stasis I mean that the passage of the contents of the intestinal canal is delayed sufficiently long to result in the production, in the small intestine especially, of an excess of toxic material, and in the absorption into the circulation of a greater quantity of poisonous products than the organs which convert and excrete them are able to deal with. In consequence, there exist in the circulation materials which produce degenerative changes in every single tissue of the body and lower its resisting power to invasion by deleterious organisms." The point of practical interest is, he said, that if the drainage scheme be made to work efficiently, or, in other words, if the delay of material in the small bowel be met effectually by mechanical means or by operative interference, the resisting power of the tissues is such that they can destroy the organisms or the poison producing these conditions, if not too advanced, or if cancer has not developed. Lane has so frequently described the mechanical factors which bring about the stasis that it need only be said here that he believes that, owing to unsuitable diet in infancy, and to the habitual assumption of the erect position, delay of fecal material takes place in the large intestine, the cesspool of the alimentary tract, or, as it can best be described, "the general drainage system of the body." In consequence of this, new membranes or resistances to downward displacement are forced by what he terms "the crystallization of lines of force" upon the surface of the peritoneum, along which strain is specially exerted. Dr. Hayes gave a summary of Lane's long list of conditions resulting from the autointoxication of chronic intestinal stasis, and stated that the marked symptoms in his own cases have been debility, loss of weight, headache, nervous irritability and emotional states, lack of concentration, drowsiness, numbness, palpitations, poor circulation, soreness of joints, constipation, and, in cases with gastric complications, bad taste, belching, regurgitation of food and acid fluid, nausea and vomiting, erosion of the teeth, and pain between the shoulder joints. Ulcer near the pylorus was a rather frequent complication. The marked physical signs have been pallor, a sallow color or slight

pigmentation of the skin, cold, moist hands and feet, and the following abdominal signs, which were very constantly present and, taken in connection with the toxic symptoms, made the diagnosis extremely simple: 1. Dilatation of the duodenum, readily mapped out by means of percussion with pressure. 2. Pressure paradox. In cases with dilated duodenum when, with the patient in the semi-recumbent or supine position, pressure is made backward and upward for about thirty seconds by the hand placed just below the umbilicus; this usually results in the undoing of the duodeno-jejunal kink present, permitting the duodenum to empty itself. 3. Inflated ileum, shown by a marked tympanitic note to the left of and below the cecum. 4. Corded colon. Frequently the left iliac colon is felt as a rope-like body directly behind the abdominal wall, a condition apparently due to spasm of the portion of bowel just above the sigmoid flexure. To what degree it should be considered abnormal is debatable. Jordan, who has done much valuable x-ray work in conjunction with Lane's investigations, has made the statement that the occurrence of duodenal distention is so constant in the subjects of intestinal stasis that he has come to regard it as a trustworthy indication, equally significant whether positive or negative. As to treatment, Dr. Hayes regards liquid paraffin or Russian mineral oil, on the use of which Lane lays so much stress, as holding first place in the way of medication. As it cannot be absorbed, it renders the stools soft, and its action as a lubricant is stated to be so efficient that it can overcome many of the troubles arising directly or indirectly from the stasis. It is not always sufficient by itself, however, and in some instances must be assisted by the administration of suitable cathartics. The food, without being coarse or irritating, should be gently laxative, and should not contain an excess of protein or a large proportion of readily fermenting elements. Exercise of various kinds, as well as massage, is of great value, and correct poise or carriage should be insisted upon,—the patient should learn to stand and sit with chest thrown forward, chin and shoulders back, and abdomen drawn upward. In most cases a suitable belt, corset or spring support is indispensable. Surgery, he believes, should not be thought of in the great majority of instances, but is indicated in the marked cases failing to respond to persistent competent medical treatment.

In this opinion Dr. Bainbridge entirely concurred, stating that the prevention of chronic intestinal stasis with its aftermath of disturbed function, disease and death, was the prime object sought in the study of this subject. The vast majority of cases, he said, should have been prevented, while hygienic and medical treatment, if instituted sufficiently early, would cure a large proportion. In many instances, however, there came a time when it became necessary to invoke the aid of the surgeon. Whether, like an expert plumber, he should patch and mend, so to speak, the defective drainage system, and thus ward off trouble, or should employ more radical measures, was a nice point to be decided according to the exigencies of the individual case. One heard of the conservative and the radical treatment, but there was no hard-and-fast distinction between the two; for the physician who waited, fearing to resort to surgery, and by this delay rendered necessary, ultimately, a severe operation, was less conservative than one who, by employing milder surgical measures at first, obviated the necessity for a radical procedure. In some cases the drainage system had been neglected until a part of the human plumbing must be removed—that was colectomy; in others it was possible to sidetrack the damaged part—that was short-circuiting. In still others the parts could be patched up; the tubes could be straightened, the angles corrected. It was often difficult to determine to just which type an individual case belonged—in fact, it had to be freely admitted that today we were feeling our way along, endeavoring to profit by experience in order to more accurately place the border-line cases. For over seven years Dr. Bainbridge has been in close touch with Sir Arbuthnot Lane, studying with him many of his cases before, during and after operation, and this observation has been supplemented by the experience gained in a large number of cases of his own; so that today he does not hesitate to short-circuit or colectomize where he is convinced that less radical measures will not suffice. The cases he described on the occasion in question were of the middle type between the strictly medical ones and those calling for radical operations, and the results of the various procedures adopted have been eminently satisfactory for, as he said, these patients, formerly suffering from the baneful effects of chronic intestinal stasis, had literally been made over through surgical intervention

based upon the mechanical causes of intestinal obstruction, as described by Lane. This subject certainly presents a wide field for research on the part of both physician and surgeon, and such work has now opened the door of hope for many a one who would otherwise have been doomed to chronic invalidism.

THE ABDERHALDEN REACTION APPLIED TO DIAGNOSIS IN PSYCHIATRY.

IN his little book of 110 pages, entitled "Schutzfermente des Tierchen Organismus," Abderhalden lays down his theory of protective or defensive ferments (Abwehrfermente). These ferments make their appearance in the blood whenever an abnormal or a foreign protoplasm is introduced into the system, and it is believed that the particular kind of protective ferment thrown off into the blood varies with the tissue from which the protoplasm is derived and is specific for that tissue. Abderhalden has also elaborated a simple method of recognizing or identifying these ferments.

As a result of this theory there has been developed a movement which certainly seems likely to bring about considerable advances in medical diagnosis and medical research. Abderhalden himself followed up his book with a paper[1] in which he gave his method of diagnosing pregnancy. Recently this principle has been extended to the diagnosis of cancer (carcinoma and sarcoma), and has been applied to the differential diagnosis of certain nervous and mental disease, particularly dementia precox, epilepsy, manic-depressive insanity and general paresis. Many other possibilities loom up before one's eyes. It is possible that later on the technic will be applicable to the diagnosis of the various infectious diseases as well as of organic diseases in various parts of the body.

The technic, very briefly stated in a general way, is as follows: The colloid albumins are removed from the substance to be used as antigen, conveniently called substrat (which may be placental tissue, thyroid gland, ovary, testis, etc., as the case may be), and a mixture of them is placed in several dialyzing tubes, in one of which the serum to be tested, and which is suspected to contain the protective ferments, which are specific for the particular antigen used, is placed. This is incubated, with the result that the albumin is decomposed, hydrolyzed and peptonized with the production of peptone, which latter passes through the dialyzer into the water in which the dialyzer tube rests, and when the peptone comes in contact with the ninhydrin solution contained in the water, a bright violet color appears. The other dialyzing tubes are used as controls, the serum of normal individuals or of individuals whose blood is not suspected of containing the specific protective ferments being tested for, is added, but no color appears.

This editorial is concerned especially with the application of the Abderhalden test to diagnosis in psychiatry. Fauser of Stuttgart published frequent papers on this subject. He used various antigens or antigen-like substances and determined their relative hydrolytic or proteolytic reaction with the sera of patients with various nervous and mental diseases. This work was followed up by that of other investigators, including Wegener, Bundschuh and Roemer, Mayer, Byer, Lampi and Fuchs, Neue, Theobauld, Steising, Fischer and Bensinger. The results up to date seem to lead one quite definitely to the following conclusions: The serum of a patient with dementia precox gives a positive reaction to—that is, they hydrolize—testicular tissue (if the patient be a male), and ovarian tissue (if the patient be a female) much more markedly than it does any other tissue. In no cases of epilepsy, hysteria or manic-depressive insanity was there a positive reaction to this test when the genital glands were used as antigens (or rather as antigen-like substances). The serum of very bad cases of dementia precox, of epileptics (at least when an attack is approaching), and of the majority of cases of general paresis present a positive reaction when human cortical tissue is used as the so-called substrat. In the final stages of paresis reactions are obtained to almost all sorts of substances or antigen-like substances, since all the organs are degenerating.

Here, then, it seems that we have found an almost certain, if not an absolutely certain, method of diagnosing dementia precox. What is more, this test may prove to be of the greatest aid in differential diagnosis in psychiatry, and may be applicable to the very early cases of dementia precox. May it not very well be that this test is applicable to the very earliest stages of incipient dementia precox or so-called prede-

[1] Diagnose der Schwangerschaft mit Hilfe der Optischen Methode und Dialysienerfahrens. *Münch. Med. Wochenschrift*, 1912, June, 1911, vol. 59, p. 1305.

mentia precox, so that we shall be enabled to pick out, from among the wayward youths in our schools, our army and navy, and our criminal courts, those individuals who are only slightly on the road to dementia precox? We can see, therefore, that this test assumes a sociological and medico-legal significance.

MEDICAL LEGISLATION. REPORT OF THE HOUSE COMMITTEE ON TUBERCULOSIS.

THE special committee appointed by the Massachusetts House of Representatives to investigate tuberculosis conditions in this Commonwealth has recently filed its report. The committee held over forty public hearings, and obtained and sifted a large amount of evidence, more or less pertinent to the matter in hand. Its report consists of a careful digestion of this evidence, with conclusions and recommendations derived therefrom.

The committee found that the law concerning the establishment of tuberculosis dispensaries has not been complied with, chiefly on account of the failure of cities and towns to agree as to what constitutes a dispensary. According to the report,

"A dispensary is an indispensable link in the system of the home treatment of the disease, where not only medicine, and other material relief, but teaching as to general hygiene and sanitation may be obtained. The dispensary is an invaluable corollary to the law of 1907, making notification of the presence of the disease compulsory."

The committee therefore recommends that the State Board of Health be empowered to determine a standard of dispensaries, and that communities then be required to conform thereto.

The most important recommendation of the report is for the establishment of a Department of Diseases Dangerous to the Public Health.

"The need of a central authority to supervise the control of tuberculosis is apparent, and has been pointed out by commission after commission. This committee recommends a single head, 'Department of Diseases Dangerous to the Public Health,' with mandatory powers, under the management of the State Board of Health. It seems advisable to use the phraseology as above, rather than simply, 'Department of Tuberculosis,' for the reason that tuberculosis is so declared by the State Board of Health, and because the construction of hospitals, sanitaria, quarantine and inspection are so similar that they should be considered at the same time if economy is to rule.

"The authority of the State Board of Health should be extended to examine all hospitals, sanitaria, asylums, homes, prisons and hospitals handling 'diseases dangerous to the public health,' which includes tuberculosis; and this committee so recommends.

"This committee has been appalled by the revelations of incompetency and weakness on the part of some local boards of health, and by the confusion of authority between them and the State Board of Health. Responsibility should be clearly placed on the State Board of Health, and it should be given authority to supervise the work of local boards."

"The presence in sanitaria, of refractory and incorrigible tuberculosis patients is the despair of superintendents and so serious a menace to the entire system, and to the health of the whole community, that this committee recommends the building of a State hospital where such cases may be segregated. The dismissal of incorrigibles only spreads the plague."

Other recommendations of the committee in its report are as follows:—

"So many communities complained to this committee of financial inability to build tuberculosis hospitals that it is recommended that the debt limit be extended for this purpose so that the hospital law on the statute books may be complied with.

"The State Board of Health should be given power to define the dispensary law and standardize as well as inspect dispensaries; also to provide a plan for a State-wide system of visiting nurses' service; also to provide supervision of all plans for the adequate ventilation of school buildings.

"In accord with the repeated recommendations of the State Board of Health, Section 39 of Chapter 75 of the Revised Laws prohibiting hospitals with 100 rods of an inhabited dwelling in an adjoining city or town, should be repealed, inasmuch as it has been demonstrated that this statute works to the detriment of the public health. This committee, after exhaustive research, has reached the conclusion that one institution, preferably that at Westfield, should be set apart for women and children in order that a beginning, at least, may be made in the proper separation of the sexes.

"In accord with the recommendation of the attorney general, the statutes authorizing the courts to order the segregation of persons afflicted with contagious diseases should be clarified."

This report is signed by all of the nine members of the committee. One of the members also submits a minority report, in which he recommends the abolition of the present State Board of Health and its replacement by a commission appointed by the Governor, this commission to

be given full power to build and maintain local tuberculosis institutions at the full expense of the State or at the joint expense of the State and each respective community.

Obviously the recommendations of the majority report merit serious attention, which they will doubtless receive at the hands of the present General Court. Whatever legislation may result, should follow only after careful and extended discussion of the situation. That work of high efficiency has already been done in dealing with the tuberculosis problems of our State in the past, does not make it impossible that improved facilities and methods for the continuance and extension of that work may not be desirable in the future.

MEDICAL LEGISLATION. THE REPORTING OF OCCUPATION DISEASES.

ON Friday, Jan. 9, a hearing was held at the State House by the joint state board of labor and industries and industrial accidents, on the question whether it should adopt, as authorized by chapter 813 of the Acts of 1913, a regulation relative to the reporting of occupation diseases and injuries by physicians. The text of the proposed regulation is as follows:—

"Under authority of section 6 of chapter 813 of the Acts of 1913 the Joint State Board of Labor and Industries and Industrial Accidents hereby requires that every physician treating a patient whom he believes to be suffering from poisoning from lead, phosphorus, arsenic or mercury or their compounds, or wood alcohol, or from anthrax, or from compressed air illness, to report within 48 hours to the State Board of Labor and Industries, the information relating thereto called for by the reporting blanks issued by the said board. Every such physician is hereby requested to make reports on the said blanks to the State Board of Labor and Industries of any patient whom he treats that is suffering from any other ailment or disease which the physician believes to have been contracted as a result of the nature, circumstances or conditions of the patient's employment."

The reporting blanks referred to are devised for the uniform record of the examination of patients with industrial diseases or injuries. The purpose of this proposed regulation is obvious as a means of securing prompt and thorough report by physicians in attendance on such patients. It is a logical adjunct to the legislative policy of dealing with occupation diseases, and as such should be adopted and enforced.

MEDICAL NOTES.

PUBLIC MEETING ON CANCER AT PITTSBURGH.—Cancer and the public efforts to reduce its ravages were discussed from many points of view on Feb. 3 at Pittsburgh, Pa., at a special open meeting in Soldiers' Memorial Hall. This gathering was arranged by the Twentieth Century Club and the Pittsburgh Academy of Medicine, with the coöperation of the American Society for the Control of Cancer as one of a series of public meetings in various parts of the country, at which representatives of the national organization will endeavor to spread the message of hope for the cure of cancer which still is to be sought only in early recognition and competent surgical treatment.

Hon. James R. Macfarlane presided and Mr. Frederick L. Hoffman, statistician of the Prudential Life Insurance Company of America made the opening address.

The Rt. Rev. Regis Canevin, Bishop of the diocese of Pittsburgh, defined the first duty of a layman to the science of medicine to give those who are engaged in it whatever encouragement he can whenever he can.

FOUR BRITISH CENTENARIANS.—Miss Ann Hutchings, who died recently at Wellington, England, is said to have been born in 1811. Mrs. Harriet Light, who died on Jan. 10, at Weston-super-Mare, was born on Sept. 13, 1813. Mrs. Cooper, who died in the same city on Jan. 7, was also born in 1813. Mrs. Clarke, of Rushden, who died recently, is supposed to have been born in 1812.

LORD STRATHCONA'S MEDICAL BEQUESTS.—The will of the late Baron Strathcona and Mount Royal, who died on Jan. 21 in London, contains bequests of $500,000 to the Royal Victoria Hospital, at Montreal, and $90,000 to hospitals in the British Isles.

SMALLPOX NEAR BALTIMORE.—Report from Maryland states that on Jan. 29, 23 cases of smallpox were reported in the vicinity of Baltimore, 21 of them being at Warren, a mill village 15 miles to the north.

SMALLPOX IN PENNSYLVANIA.—Report from Erie, Pa., states that on Feb. 1 there were 90 cases of smallpox in North East, a neighboring town in Erie County, with a population of 2000. All the inhabitants are now being vaccinated.

THE MAGEE HOSPITAL.—It is announced that work has been begun on the erection of the Magee Maternity Hospital at Pittsburgh, Pa., which is expected to cost $800,000, and which will be affiliated with the University of Pittsburgh Medical School.

BOSTON AND NEW ENGLAND.

INFECTIOUS DISEASES.—Cases of infectious diseases reported to the Boston Board of Health for the week ending Feb. 3, 1914: Diphtheria, 61, of which 1 was non-resident; scarlatina, 95, of which 3 were non-resident; typhoid fever, 20; measles, 52; tuberculosis, 47, of which 2 were non-resident.

The death-rate of the reported deaths for the week was 19.45. The deaths of 19 "Arcadia fire" victims are included in this rate.

MASSACHUSETTS ASSOCIATION OF BOARDS OF HEALTH.—The annual meeting of the Massachusetts Association of Boards of Health was held in Boston on Jan. 29. The principal address was on "Child Hygiene," by Dr. William J. Gallivan, who pointed out that the infant mortality in this city has declined from 126 per 1000 births in 1911, to 117 in 1912, and only 107 in 1913. The following officers were elected for the ensuing year: President, Dr. James C. Coffey, of Worcester; vice-presidents, Dr. Milton J. Rosenau, of Brookline, Mass., and Dr. Charles V. Chapin, of Providence, R. I.; treasurer, Dr. Francis C. Curtis, of Newton; and secretary, Dr. Francis H. Slack, of Boston.

A NEW PREGNANCY CLINIC.—On Thursday of last week, Feb. 5, the Boston Milk and Baby Hygiene Association opened at the Peter Bent Brigham Hospital a pregnancy clinic, under charge of Dr. Arthur B. Emmons, 2nd, of this city. The nursing service will be supplied by the Boston Instructive District Nursing Association.

TWO LIVING CENTENARIANS.—Mrs. E. P. MacGray, of South Scituate, R. I., who is said to have been born on Feb. 2, 1811, in Barnstable, Mass., celebrated last week her supposed 103rd anniversary. Her health is excellent.

Mrs. Margaret E. Jordan, of Malden, Mass., who is said to have been born in February, 1814, celebrated recently her supposed centennial anniversary. She walks outdoors every day, and is in excellent general health.

SMALLPOX IN PORTLAND.—Report from Portland, Me., states that on Feb. 4, there were in that city 15 cases of smallpox. All the local schools have been indefinitely closed, and the public is advised not to frequent places of assembly and amusement.

ARMY NURSES' MEMORIAL.—On Thursday, Feb. 12, a memorial is to be dedicated in the Massachusetts State House to the army nurses of the Civil War.

"The memorial is a statue representing a wounded soldier reposing in the arms of an army nurse. The inscription is: "To the army nurses from 1861 to 1865. Angels of mercy and life amid scenes of conflict and death. A tribute of honor and gratitude from the Massachusetts Department, Daughters of Veterans, 1914."

HOSPITAL BEQUESTS.—The will of the late Mary A. Towars, of Brookline, Mass., which was filed on Jan. 30 in the Norfolk Registry of Probate, contains bequests of $200 each to the Boston Nursery for Blind Babies and the Boston Floating Hospital.

NEW YORK.

ENDOWMENT OF MEDICAL EDUCATION.—The annual dinner of the faculty and directors of the New York Post-Graduate Medical School and Hospital was held on Jan. 28. The president, Dr. J. F. McKernon, was toastmaster, and among the speakers was Prof. W. H. Welch of Johns Hopkins University. In his remarks the latter expressed his regret at the lack of endowment of medical colleges. "I would be the last," he said, "to say a word against institutions like the Rockefeller Institute and the Carnegie Institute at Washington, which have fully justified their existence by their contributions to knowledge. But there is not a similar acknowledgment of the need of endowing medical education, and it is a narrow course to endow research work and not to endow medical education, in which research work is rooted."

REPORT OF STONY WOLD SANATORIUM.—The thirteenth annual meeting of the Stony Wold Sanatorium Corporation was held on Jan. 28, when the principal address was made by George McAneny, president of the board of aldermen. The reports of the institution, which is in the Adirondacks and cares for women and children with incipient tuberculosis, showed that during the past year 230 patients had been treated, and

that 146 patients had been discharged as cured. Of all who have ever been discharged from the sanatorium, it was stated, between 60% and 65% are working and apparently in good health.

MEETING OF ASSOCIATED PHYSICIANS OF LONG ISLAND.—The sixteenth annual meeting of the Associated Physicians of Long Island was held at the library building of the Medical Society of Kings, Brooklyn, on Saturday afternoon, Jan. 31, and at the scientific session a paper on "Practical Points in the Interpretation and Management of Low Blood Pressure," was read by Dr. E. E. Cornwall of Brooklyn, and one on "Original Uses of the Bone Graft; with a Report of 325 Cases," by Dr. F. H. Albee of Manhattan. In the evening a dinner was held at the Hamilton Club, the principal address at which was made by Dr. William Francis Campbell, of Brooklyn, president of the New York State Medical Society.

A MEDICAL POSTMASTER.—Dr. William H. Murray has been appointed postmaster of the city of Albany by President Wilson, Dr. Murray was graduated from the Albany Medical College in 1869, and is still in active practice.

NURSING IN MUNICIPAL HOSPITALS.—The hospital investigating committee of the Board of Estimate and Apportionment, of which George McAneny, president of the Board of Aldermen, is chairman, has submitted two more sections of its report, both in regard to the nursing in the municipal hospitals. One of the recommendations is that a schedule should be established calling for the employment of one nurse for each four beds in the smaller hospitals having frequent admissions, and of about one for each five beds in the larger hospitals, which care for the more prolonged cases. The present conditions are described as unsatisfactory, and it is stated that, while nursing associations are endeavoring to improve conditions and to meet the demand for nursing by educating a supply of well-trained, competent nurses, the supply is by no means adequate to the needs, and it is an open question whether or not some form of training should be offered which would attract and equip a larger number of women for the nursing field; a form of training which would not encroach upon the field of the highly trained nurse.

VALUE OF STATISTICAL MATERIAL.—The criticism has been made that the value of much of the statistical material published by the City Health Department in its weekly and monthly bulletins is greatly impaired because its form is such as to render comparison with other years difficult, or even impossible. This criticism does not apply, however, to the tables prepared by the Bureau of Records, which have long been published in their present form and which are, therefore, readily available for purposes of comparative study. Consequently, the department has, in its *Weekly Bulletin*, begun the publication, in the form of fixed tables, of certain statistical material relating to its work, and hopes thereby to render the bulletins more serviceable to students of public health. The first installment of this relates to typhoid fever in the last quarter of 1913, and gives the figures concerning the following points: Cases reported (true cases—no cases); deaths; blood sent to laboratory (positive—negative); treated at home; treated at hospital; contact; probably out-of-town infection; additional cases with out-of-town history; total with out-of-town history; number of persons exposed to a case in family; immunization refused; immunization accepted.

APPOINTMENTS AT COLUMBIA UNIVERSITY.—At a meeting of the trustees of Columbia University, held on Feb. 2, it was announced that Dr. George E. Brewer, professor of clinical surgery, had been appointed professor of surgery, in the place of Dr. Joseph A. Blake, resigned. This professorship carries with it the important position of head of the surgical division of the Presbyterian Hospital. Dr. Walter B. James, professor of clinical medicine, was, at his own request, retired from the faculty of the medical department. He will still, however, retain his professorship, and continue to direct certain lines of research work. Among the gifts announced at the meeting was one of $2,500 from Dr. John A. Fordyce, for special equipment at the Vanderbilt Clinic.

CRIMINAL NEGLIGENCE.—As the result of a coroner's inquest in the Bronx, John C. Wessels, Jr., and a Christian Science healer, Mrs. J. D. McClintock, were, on Feb. 2, held in $1,000 bail each, on a charge of criminal negligence. A child of Wessels,' 20 months old, died from diphtheria on Jan. 17, under the attendance of the healer, and at the inquest Dr. S. D. Hub-

bard of the Department of Health testified that after the child's death the father refused to permit the administration of antitoxin either to himself or to his other children. He also reported that throughout the baby's illenss a sister, twelve years of age, was allowed to attend the public school where she was a pupil.

ANOTHER CASE OF TYPHUS.—On Jan. 28 a case of typhus fever was discovered by health officers of this port aboard the French steamer *Rochambeau*, which arrived on Jan. 26 from Havre. The patient and 102 of his immigrant companions were placed in quarantine at the Hoffmann Island Hospital. This was the sixth case of typhus fever detected at this port during the month of January.

HARVEY LECTURE.—The eighth of the current series of lectures before the Harvey Society will be delivered on Saturday evening of this week, Feb. 14, at the New York Academy of Medicine, by Prof. J. J. R. Macleod, of Western Reserve University, on "Recent Work on the Physiological Pathology of Glycosuria.

THE HOME HOSPITAL EXPERIMENT.—The New York Association for Improving the Condition of the Poor has just issued a publication (No. 78) entitled "The Home Hospital Experiment," being a statement of the "methods, results, and comparative cost during the first year (1912-13) in the combined home and hospital treatment of families made dependent by tuberculosis.

2. Chace and Myers report on a study of the enzyme activity of duodenal juice obtained with the Einhorn tube. They find that the activity of the amylolytic, lipolytic and proteolytic enzymes of this juice is subject to considerable variation under normal conditions. It is not influenced by the acidity of the gastric juice. In a case of chronic pancreatitis, the amylolytic and proteolytic activity was entirely negative and the lipolytic activity comparatively weak. The absence of pancreatic enzymes from the duodenal juice would therefore appear to be positive evidence of either pancreatitis or non-potency of the pancreatic ducts.

3. Whipple studied the blood in a series of cases of hemorrhagic disease of various forms. He is more convinced than ever by this further study that antithrombin is a factor of importance in cases of bleeding. He finds that the antithrombin-prothrombin balance in the blood is in delicate equilibrium, but under normal conditions there are strong factors which can preserve this balance. Under disease conditions this balance may be temporarily or permanently upset. The prothrombin factor is rarely involved, but may drop to a low level and cause hemorrhagic symptoms. The antithrombin factor is frequently involved, the amount of excess determining the degree of hemorrhage. Antithrombin may fall below normal and cause a tendency to vascular thrombosis. It is highly probable that under certain conditions liver injury or disease may be associated with an excess of antithrombin in the blood capable of giving hemorrhagic symptoms. True hemorrhagic disease is rarely associated with obstructive icterus. In these rare cases we may presuppose some liver disease and an upset in the antithrombin-prothrombin balance. Certain substances in the blood will cause an overproduction of antithrombin, due probably in great part to the stimulation of the liver. This is the cause of hemorrhagic symptoms in septicemia, endocarditis, pneumonia and miliary tuberculosis. In disease of the blood-forming organs, the blood-forming tissues are probably not directly concerned in the excessive antithrombin production, as this element is much in excess in cases of anemia with complete marrow aplasia. Treatment of hemorrhagic disease should follow a careful analysis of the blood. In cases of low prothrombin serum rich in this element is indicated, intravenously or, even better, by direct transfusion. Treatment of antithrombin cases is very difficult. At present direct transfusion seems to offer the greatest hope of permanent benefit.

4. Kolmer, Lanbaugh, Casselman and Williams report on studies of syphilis antigens. In the order of efficiency in practical serum diagnosis of syphilis, they arrange the various extracts in the following order: (1) cholesterinized alcoholic extracts of human, pig and beef heart; (2) plain alcoholic extracts of known syphilitic liver; (3) acetone-insoluble lipoids (Noguchi), (4) plain alcoholic extracts of human, pig and beef heart; (5) acetone extract of syphilitic liver; (6) plain alcoholic extract of normal liver. The best results are obtained by using several

antigens with each serum, including plain and cholesterinized extracts.

6. Vogel and McCurdy discuss the value of blood transfusion in pernicious anemia and report six cases. They believe that transfusion of physiologically unaltered blood is one of the most promising forms of palliative treatment available in this disease. The measure should not be postponed until the patient is in a desperate condition. Large transfusions may be injurious and it is probable that more benefit is to be expected from small doses introduced at intervals to be determined by the progress of the patient. The enumeration of the reticulated cells by the method of vital staining is a reliable means of watching the hemopoietic activity of the bone marrow and the effects of various therapeutic measures upon it.

8. McLester studied the effect of atophan on the uric acid of the blood and the urine. He finds that the amount of endogenous uric acid in the blood of different individuals varies widely, but for a single individual the figure is a constant one. Atophan increases renal activity and exerts a selective stimulating influence on uric acid excretion, while it simultaneously reduces the uric acid of the blood. Its influence on uric acid metabolism seems to be limited to its power of transferring uric acid from the blood to the urine.

10. Barach studied the blood in epidemic parotitis. He finds that in fully developed uncomplicated cases of this disease there is a marked leucopenia with the polynuclears relatively and absolutely decreased and the lymphocytes relatively and absolutely increased. Eosinophiles are very scarce.

11. Janeway gives the results of an 18-months clinical study of cardiovascular disease with hypertension, his object being to throw light on prognosis in these cases. He finds that the most prominent symptoms associated with high blood pressure are circulatory rather than renal. The disease underlying high arterial pressure is predominantly a disease of the circulatory system, whether primary or secondary to preceding inflammatory nephritis. Death in these cases (in private practice) occurs most often by gradual cardiac insufficiency, next often with uremic symptoms, by apoplexy, by complicating acute infection, by angina pectoris, from unrelated causes, with acute pulmonary edema, with cachexia.

The early symptoms have an important prognostic significance. The early occurrence of symptoms of myocardial weakness, especially dyspnea, indicates a more than 50% probability of eventual death by cardiac insufficiency. The early occurrence of anginoid pain on exertion does not indicate a probability of death in an anginal paroxysm for more than one-third of the patients, but does indicate a probable cardiac death of some type. Polyuria, particularly if nocturnal, indicates the probability of a uremic death for more than 50% of the patients. Headache indicates the probability of a uremic death for more than 50% of the patients, and death from apoplexy for a considerable number of the remainder. Progressive loss of weight is a bad prognostic sign. Systolic blood pressure persistently above 200 mm. indicates a greater probability of death by uremia or apoplexy. The average duration of life in the group of patients studied was four years for the men and five for the women. One-fourth of the whole number, however, lived more than ten years from the appearance of the first symptom. [L. D. C.]

12. CRAMER. *A New Drug for the Treatment of Whooping Cough ("Droserin").*
13. KAYSER. *The Therapeutic Importance of Calcium.*

5. The author has been able to find in the literature reports of fecal vomiting in several conditions besides obstruction,—typhoid, scarlet fever, spasm of the colon, and hysteria; but no record of such occurring in tabes, as in his case. The patient was a man of 53, with a history of luetic infection, and presenting many of the symptoms and most of the signs of tabes. He had, at irregular intervals, extremely severe gastric crises, during several of which he had perfectly typical fecal vomitus. The author could rule out satisfactorily the presence of a possible fistula between the stomach and either large or small intestine, and presents this case merely as an interesting exception to the rule of stercoraceous vomiting being pathognomonic of obstruction—whether mechanical or paralytic. [R. H. M.]

DEUTSCHES ARCHIV FÜR KLINISCHE MEDIZIN.

DECEMBER 16, 1913.

1. *GRAFE, E. *The Effect of a Continued Diet Rich in Carbohydrates and Without Albumen upon the Metabolism of Man and Animals.*

2. MANDELBAUM. *Changes in the Cerebrospinal Fluid in Tubercular Meningitis.*
3. *PFANNMÜLLER. *Influence upon Nitrogen Metabolism in Infectious Fevers by Increased Carbohydrate Intake.*
4. BELTZ, L. *Leukemia, with Special Regard to the Acute Type.*
5. BURNS, O. *Experimental Study of the Phenomena of Cardiac Weakness after Over-exertion.*

1. Grafe calls attention to the fact that in most of the work in regard to additions of excesses of sugar to the diet with subsequent increase in stored glycogen and fat and increase in weight there is also an increase in nitrogen as well as carbohydrate. He mentions the peculiar findings of certain men that carbodrate diet alone without nitrogen does not cause increase in weight, but usually a diminution. This paper is a report on the study of a series of men and animals in regard to their weight, nitrogen metabolism, water balance, and heat production. These subjects have been fed on a diet much above the caloric needs with the increase composed of carbohydrates without albumen. He found that they lost in weight in practically all instances. The loss of weight was due to a loss in water balance at the start and after a week or so to a marked increase in heat production. This increased oxydation was most marked in the swine, less so in the dogs, and least in man. His article is accompanied by a long series of tables in which the results are placed in detail.

3. Pfanmüller has reported the results of some studies on nitrogen excretion which were undertaken to see whether in febrile conditions, as in health, a saving of nitrogen excretion could be produced by the addition of a rich carbohydrate diet. His studies show that in fever caused by the pus-forming bacteria a saving of from 15 to 40% of nitrogen destruction can be produced by this means, as contrasted with the 10% saved by the same method in health.
[C. F., JR.]

WIENER KLINISCHE WOCHENSCHRIFT.

No. 44. OCTOBER 30, 1913.

1. BASTEL, T. *The Significance of Constitutional Conditions.*
2. BRINNER, A. *The Advisability of Gastroenterostomy and Resection in Ulcus Ventriculi Remote from the Pylorus.*
3. *NOVAK, T., AND PORGES, O. *The Acidity of the Blood in Osteomalacia.*
4. JELLINEK, S. *The Significance of the Nature and Intensity of Strong Electric Currents in Relation to Their Reaction on the Animal Body.*
5. v. MASSARIE, AND KRONENFELS, G. *The Treatment of Frostbites in Time of War.*
6. PAUL, E. *The Extraction of Foreign Bodies from the Air-Passages.*
7. KVOKIEWICZ, A. *The Benzol Therapy of Leukemia.*

3. The authors draw conclusions as follows: There is a relation between acidosis and osteomalacia, but the acidosis seems an accompanying rather than an etiological factor. The carbon dioxide tensions of the alveolar air may be used as an indicator of the acidity of the blood. In normal pregnancy there is occasionally as low a CO_2 tension, *i.e.* relatively high acidity of the blood as in osteomalacia. The remainder of the article takes up the well-known theory of the "perverted ovarian secretion," cause of osteomalacia and its cure by castration. [F. S. K.]

No. 45. NOVEMBER 6, 1913.

1. HESS, L., AND MÜLLER, H. *The Ultimate Fate of Destroyed Red Blood Cells.*

5. *SACHS, O. *Early Treatment of Syphilis.*
6. SPITZER, T. *Case Histories of Syphilis.*
7. SCHWARZ, G. *The Therapy of Secondary Rays.*

5. The treatment of syphilis, the author concludes, offers better prospects the earlier it is begun. Such treatment consists in extirpation or cauterization of the primary sore, followed by combined mercury and salvarsan treatment continued under a sufficient period under control of the Wassermann reaction. According to the observations of the author, 101 cases over a period of one to six years, the combined treatment gives by far the best results as compared either with mercury or salvarsan alone. [F. S. K.]

41. LOEPP, W. H. *Luxatio Femoris Centralis Traumatica.*

36. Veit's article reviews the work which has been done on Meckel's diverticulum, and adds two cases. Persistence of the omphalo-mesenteric duct may cause intestinal obstruction by mechanical means or may be the seat of an acute inflammatory condition. Normally the duct disappears in the second month of intrauterine life, but when it persists may be found at birth as a blind sac ending free within the abdomen, as a sac connected by a band with the interior abdominal wall, as a channel between the intestine and the navel, or even as an open canal extending into the umbilical cord. In some cases in which the canal itself is obliterated, "rests" of mucous membrane occur at the umbilicus, where they form granulomata, or along the tract of the obliterated duct, where they form cysts. Veit's cases were both in young infants. In the first, a fecal fistula appeared at the navel, and through this fistula the mucosa of the diverticulum prolapsed. At operation the diverticulum was removed, but a fecal fistula persisted and the child died a few weeks later. In the second case, there was also a fecal fistula at the umbilicus. Through this the diverticulum was extruded, and was followed by several cm. of true intestinal wall. This became strangulated and the child died without being operated.

Veit advises operation early in patent omphalo-mesenteric duct cases, as later the child becomes weakened and is a poorer risk. There is also the chance that the gut may become strangulated, requiring resection, which is, of course, a much more serious operation. In 22 operations for patent Meckel's diverticulum, Straeter had a mortality of only 10%. [G. G. S.]

Miscellany.

A FRENCH FEMALE XIPHOPAGUS.

IN a recent issue of the JOURNAL we noted the case of a new pair of so-called Siamese twins, born in Paris on Nov. 27, 1913. The case was recently presented by Dr. LeFilliâtre before the French Academy of Medicine, and the following description of it was published in a recent isue of the *British Medical Journal*.

"The two girls, who are in good health, are united at the base of the sternum by a fleshy cylinder which appears to enclose above a sort of semi-rigid bridge and below two parallel fibrous tracts. Radioscopic examination, after ingestion of bismuth by one of the children, shows that the digestive canals are independent of one another, although in the fleshy part there is a canal which brings the two abdominal cavities into communication, by which the alimentary tube passes at times, when contractions occur, out of the abdomen of one child, causing a hernia into the other child, and even reaching to its liver. It cannot be said that any union between the two livers, such as has been found previously in such monsters, exists. A special interest attaches to this case, inasmuch as all those hitherto described were anterior to the discovery of radioscopy of the alimentary canal by the use of bismuth. The operation to separate the children has not yet been performed (though it does not seem to present any serious difficulty) because one of the children is affected with umbilical suppuration, no doubt extending to the umbilical vein. This constitutes a condition of infection unfavorable to present surgical intervention. Meanwhile, several examinations have been made, which have led to curious results. Blood examinations show a great difference in the cytologic condition of the two children; the erythrocyte and leucocyte counts, the pulse beats, even the temperature records, differ considerably in the two bodies, showing that the circulations are independent, at least in their

larger passages. The child affected with umbilical suppuration shows a greatly increased leucocytosis over the other, which is easily explainable; but this infection reacts only on herself, and in no way affects the general condition of her fellow. One child may show some slight febrile movement as well as diarrhea, without the other one suffering any indisposition. There is only one symptom which always extends from one child to the other—insomnia."

RELATIONSHIP OF TYPHOID AND TUBERCULOSIS.

Seven years ago Reincke of Hamburg and Mills of the United States first called attention to the fact that wherever the typhoid incidence of a community is reduced by improvement of its water supply, the incidence of other diseases, notably tuberculosis, is also simultaneously reduced. Hazen, Sedgwick and MacNutt made further observations and contributions on this subject, but left undecided the cause of this interesting phenomenon.

In the January issue of *American Medicine*, Woodruff publishes detailed data aiming to prove a relationship between tuberculosis and typhoid; and in the issue of *Science* for Jan. 30, he published a preliminary note summarizing as follows the theory of his explanation.

"It has been found that tuberculosis follows typhoid fever far more frequently than physicians have suspected, and moreover, the tuberculosis mortality curve of a nation is almost always parallel to that of typhoid fever. Cities do not show such a close agreement as the country as a whole, because consumptives quite commonly leave the city to die elsewhere. As far as the very defective statistics permit a conclusion, it is to the effect that conumptives have had much more typhoid fever than the rest of the population. We have long known of the serious after-effects of typhoid fever, but only recently have a few physicians been calling attention to the far-reaching nature of these sequelae. Tuberculosis is only one of these results. That is, by reducing typhoid fever in any way whatever we save far more from death by numerous other conditions due to the lessened resistance caused by the typhoid infection. The purification of a water supply is then only one of the numerous ways of reducing tuberculosis.

"The explanation of the phenomenon is evident. By personal inquiries of physicians in the United States, Germany, Switzerland, France and Great Britain, I find that the following facts seem proved to the minds of those who by special study are competent to form an opinion. Babies are born free of tuberculosis, but begin to acquire it as soon as they can crawl around, pick up the bacilli with dust and dirt, and immediately convey them to the mouth, after the manner of all babies. These germs are weakened or attenuated by sunlight, drying, etc., and are not able to spread actively, though they establish themselves. Those which are taken in by the phagocytes have the same effect as vaccination and cause the production of antibodies, which make us all more or less immune to infection by virulent bacilli. If a baby is infected by fresh virulent bacilli from a nurse, before its immunity is produced, it dies of rapid disseminated tuberculosis, but an adult is not harmed by the virulent bacilli he takes in. Indeed, there is no incontrovertible evidence that any adult ever acquires tuberculosis. If one develops active tuberculosis, it is not a new infection, but an activation of latent lesions he has been carrying since childhood. Something has happened to him which has caused a temporary lessening of his antibodies and allowed the latent tuberculosis to spread—and nothing is more potent in doing this than the infections like measles, whooping cough and typhoid fever. Without these activating causes a man may lose immunity very slowly by improper food, mental and physical exhaustion, living in badly ventilated rooms, lack of outdoor exercise and a thousand other ways of lowering general health, but if one in such a condition does acquire another infection, like pneumonia, typhoid fever or influenza, his chances of becoming actively tubercular later are very large. Post-mortems of children almost always reveal tubercle, no matter what the disease was which caused death. Post-mortems of adults always show healed lesions, proving that at some time in our lives each of us lost resistance sufficiently to allow the lesions to become active, though we were later cured by a re-establishment of the immunity. One-eighth or one-tenth of us are unable to re-establish it and perish from tuberculosis. These facts are bound to modify the anti-tuberculosis crusade most profoundly.

"Savages, living an outdoor isolated life, have no chance to encounter tubercle bacilli and consequently do not become immune. When they do come in contact with a case they run a rapidly fatal course—generally if not always disseminated or miliary. That is, tuberculosis did not become a human affliction until long after we began to cluster together in confined shelters—possibly not until after we began to construct huts, 'dugouts,' and houses."

NOTICE.

Commonwealth of Massachusetts.—A conference in Modern Developments in Mental Nursing will be held in the Assembly Room at the Psychopathic Hospital, Monday 4–6 p. m., February 16, 1914.

1. Introductory remarks, Walter Channing, M.D., Chairman, Board of Trustees, Boston State Hospital.
2. "The Ideal Training of the Mental Nurse," Miss M. Adelaide Nutting, R.N., Director, Department of Health and Nursing, Teachers College, New York.
3. "The Nursing Component in the Recovery of Cases at the Psychopathic Hospital: An Analysis of

the First One Hundred Cases," E. E. Southard, M.D., Director, Psychopathic Hospital.

4. "First Impressions of the General Hospital Nurse on Visiting the Psychopathic Hospital," Miss Mary L. Gerrin, R.N., Acting Superintendent of Nurses, Psychopathic Hospital.

5. "A Comparison of the Drug Lists in General and Mental Hospitals," Donald Gregg, M.D., Assistant Physician, Out-Patient Service, Psychopathic Hospital.

6. "Constructive Mental Nursing," Herman M. Adler, Chief-of-Staff, Psychopathic Hospital.

7. "On the Incidence of Bedsores in Thirteen Hundred Mental Cases," Myrtelle M. Canavan, M.D., Pathologist, Boston State Hospital.

8. "The Question of Diet for the Insane in the Light of the Almost Constant Occurrence of Chronic Bright's Disease in Subjects Dying Insane," M. M. Canavan, M.D., and E. E. Southard, M.D.

9. "The Art of Companionship in Mental Nursing," Henry R. Stedman, M.D., Chairman, Board of Trustees, Taunton State Hospital.

10. "The Factor of Influencibility in Voluntary Admissions at the Psychopathic Hospital," George E. Eversole, M.D., Assistant Physician Psychopathic Hospital.

11. "The Problems of Mental Nursing from the Standpoint of the Medical Social Worker," Miss Ida M. Cannon, R.N., Head Worker, Department of Social Service, Massachusetts General Hospital.

12. "The Male Nurse," George T. Tuttle, M.D., Superintendent, McLean Hospital.

A brief recess will be taken at 5 o'clock for the convenience of early goers and late comers.

MASSACHUSETTS GENERAL HOSPITAL.

A surgical meeting open to the medical profession will be held ot 8.15 p. m., on Friday, Feb. 20, 1914, in the lower amphitheatre of the Out-Patient Department, Massachusetts General Hospital. Entrance on either Blossom or Fruit streets. The following papers will be presented:

" Cancer of the Uterus," by Dr. Farrar Cobb.

"A Study of Blood-Pressure in Hysterectomies and Other Radical Operations," by Dr. Harold Giddings.

An orthopedic meeting, open to the medical profession, will be held at 8.15 p. m., on Friday, Feb. 13, 1914, in the lower amphitheatre of the Out-Patient Department, Massachusetts General Hospital. Entrance on either Blossom or Fruit Streets. The following papers will be presented:

1. "Causes of Scolosis," by Dr. Z. B. Adams.

2. "Back Pain and Its Diagnosis," by Dr. Harry Platt.

3. "X-ray Diagnosis of Lesions of the Lumbar Spine and Sacro-iliac Joint," by Dr. C. Hermann Bucholz.

4. "Use of Plaster Backs in Post-operative Backache," by Dr. John McCartin.

SOCIETY NOTICES.

BOSTON MEDICAL LIBRARY IN CONJUNCTION WITH THE SUFFOLK DISTRICT MEDICAL SOCIETY.—General meeting, John Ware Hall, Wednesday, Feb. 18, 1914, at 8.15 p. m.

"The Interrelationship of and the Lesions Produced by Various Streptococci, with Special Reference to Endocarditis," Dr. Edward C. Rosenow of Chicago. Discussion will be opened by Drs. M. J. Rosenau, S. B. Wolbach and W. H. Smith.

Light refreshments after the meeting.

ROGER I. LEE,
WILLIAM P. GRAVES,
CHANNING FROTHINGHAM, JR.
Committee on Medical and Social Meetings for the Boston Medical Library.

THE NEW ENGLAND BRANCH OF THE AMERICAN UROLOGICAL ASSOCIATION.

There will be a meeting of the Association on Tuesday, Feb. 17, at 8.15 p. m., at the Boston Medical Library.

Program.

1. Demonstration of instruments and specimens, and reports of cases.

2. Symposium. The genito-urinary tract as a factor in the production of chronic toxemias and joint lesions: (a) "Physiology and anatomy of the seminal vesicles in regard to the treatment of their lesions," Dr. William C. Quimby, Boston; (b) "Recent studies in the pathology of the seminal vesicles," Dr. J. D. Barney, Boston; (c) "Arthritis associated with genito-urinary lesions," Dr. E. G. Brackett, Boston; (d) "Indications for operation on the seminal vesicles, with suggestions as to the technic and the results so far obtained," Dr. J. Bentley Squier, New York; (e) "Operative treatment of inflammatory and tuberculous lesions of the seminal vesicles," Dr. Hugh H. Young, Baltimore. Discussions by Dr. C. F. Painter, Dr. Hugh Cabot, and others.

RICHARD F. O'NEIL, *Secretary.*

THE BOSTON SOCIETY OF MEDICAL SCIENCES.—The next meeting will be held on Tuesday evening, Feb. 17, 1914, in the amphitheater of the Administration Building of the Harvard Medical School, at 8.15 o'clock.

Program: Drs. S. B. Wolbach and R. S. Austin: "A New Filterable Spiral Organism from the Human Colon." (20 minutes.)

Dr. Carl TenBroeck: "The Antigenic Properties of Racemized Egg Albumin." (15 minutes.)

Dr. Theobald Smith: "Experimental Hematogenic Simulating Bronchogenic Tuberculosis." (30 minutes.)

THOMAS ORDWAY, *Secretary and Treasurer.*
Harvard Medical School.

THE HARVEY SOCIETY.—The eighth lecture will be delivered on Saturday, Feb. 14, at 8.30 p. m., at the New York Academy of Medicine, 17 West 43d Street, by Prof. J. J. R. MacLeod, Western Reserve University. Subject: "Recent Work on the Physiological Pathology of Glycosuria."

RECENT DEATHS.

DR. VON BEVERHOUT THOMPSON, a highly esteemed practitioner of New York who retired from practice some years ago on account of ill health, died at his country residence near Poughkeepsie on January 19. He was a native of Maryland, and was graduated in the District of Columbia in 1867.

DR. WILLIAM H. HANFORD, who died recently in Brooklyn, was born at Saratoga Springs, N. Y., in 1825, the son of a physician. He graduated in 1846 from New York University Medical School. In 1853 he settled in the practise of his profession at Brooklyn. He was a member of the American Institute of Homeopathy, and of the New York State and Kings County Homeopathic Medical Societies. He is survived by his widow and by one son.

DR. THOMAS PEDDIE of New York died on January 20. He was graduated from Bellevue Hospital Medical College in 1875, and for twenty-three years served as a medical inspector in the City Health Department.

DR. GARFIELD H. ATWOOD, who died on Feb. 1 at Waterbury, Conn., was born in 1831. He received the degree of M.D., in 1844 from Yale. He immediately settled at Woodbury, and continued there in the practise of his profession until 1904. He is survived by his daughter.

Original Articles.

THE SIGNIFICANCE OF INTRA-ABDOMINAL "BANDS," "FOLDS" AND "VEILS."*

BY WILLIAM SEAMAN BAINBRIDGE, A.M., Sc.D., M.D., NEW YORK.

INTRODUCTORY REMARKS.

WHEN I first began, about eight years ago, to study the various bands, folds, membranes, and other adventitious structures found within the abdomen, and to consider the relationship of these to chronic intestinal stasis, little heed was paid by the general body of the medical profession to this field of investigation in which Sir Arbuthnot Lane, of London, is unquestionably the pioneer. It is, therefore, with keen pleasure that I have watched the awakening of interest, of which this symposium is, in a way, the culmination. A few years ago Lane's statements with reference to the existence of these newly formed structures, to which he gave the name, "evolutionary bands," were received with incredulity, and his conclusions with regard to relationship between these tissues and chronic intestinal stasis were met with skepticism. Now, however, as he has told us, so many "bands," "folds," "veils" and "membranes" are being found within the abdominal cavity that some maintain that they cannot possibly be the cause of chronic intestinal stasis.

While doubt concerning their existence has been practically eliminated by repeated verification on the part of many observers, the origin and effect of these structures continue to call forth differences of opinion.

There has become manifest, too, in the development of the entire subject, that unfortunate tendency which so often characterizes scientific work, to label things with the names of those who first specifically described them. And so, we have the "bloodless fold of Treves," the "parieto-colic peritoneal fold of Jonnesco and Juvara," the "genito-mesenteric fold of Reid," the "ileo-pelvic band" and other "bands" of Lane, and the newly-formed veil of peritoneum"—"Jackson's membrane"—the last being the special subject for discussion on this occasion.

It seems to have escaped the attention of many investigators that Sir Arbuthnot Lane, in 1901,[1] first called attention to a "large vascular peritoneal apron" having an attachment to the abdominal wall outside the cecum and colon, and extending inwards over it and being firmly attached to its surface." "Its object," he said, "is clearly to limit the range of movement of the cecum, and to control its distention." This vascular peritoneal apron, according to Lane, is continuous with bands deep in the loin. These bands of peritoneum, which are sometimes spoken of as adhesions, are attached posteriorly deeply in the loin, and are often very strong, giving rise to obstruction of the upper part of the ascending colon, and producing distention and hypertrophy of the cecum. Aside from the inflammatory cases, where the adhesions are the sequel of peritonitic or appendiceal processes, other cases were explained by him as having apparently developed in consequence of an habitual distention of the cecum, as the result of constipation. This state of affairs, he maintained, is very common but not sufficiently recognized.

In 1903[2] Lane again called attention to the subject of this interference with the drainage of the intestinal canal, and again emphasized the vital importance of its recognition. He contended that the free passage of the intestinal contents through the hepatic flexure is interfered with by the development of a mesentery which is attached to the outer surface of the cecum, ascending colon, and the hepatic flexure. He presented a diagram showing the "bridles" formed by the shortening up of the longitudinal fibres on the front of the ascending colon, stating that these "bridles" are so marked in some cases as to require to be partly divided in order to restore the colon and cecum to their normal position and their capacity for the efficient performance of their function.

When I first began to study these conditions with Lane, this peritoneal apron to which your distinguished president subsequently gave the name, "pericolic membrane," as well as the various other folds and bands which are commonly found in chronic intestinal stasis, were demonstrated to me by him numbers of times at Guy's Hospital. They were not given specific names, and were not considered by him as separate entities, each with its own particular sphere of activity in the production of abnormal conditions within the abdomen, and each invested with its own particular set of symptoms; he rather considered them as parts of the great whole,—the causation and symptomatology of chronic intestinal stasis.

Lane's dominant idea in studying the cases which have come to be known under the diagnostic term of chronic intestinal stasis, was to work back from the widely divergent manifestations which we now consider to be the symptom-complex of stasis, to the underlying cause or causes. At the same time, naturally, he was working in the opposite direction, from the abnormal intra-abdominal manifestations which have come, carelessly, and without his approval, to be known as "Lane's bands," and "Lane's kinks," to the possible pathological effects produced by these. Coincidentally, of course, he studied the pathogenesis of these intra-abdominal tissue formations.

Thus Lane, recognizing the existence of these

* Presented by invitation, with lantern slide illustrations, before the twenty-third annual meeting of the Western Surgical Association, December 19, 1913, at St. Louis, Mo.

pathological structures within the abdomen, studying their pathogenesis, tracing their relationship to a wide variety of pathological manifestations, and developing a system of preventive and correctional measures, has played the rôle of the true pioneer, pointing the way to a new field for exploration, a new territory for useful endeavor. Lane, in other words, has stood on the mountain-top, so to speak, and has swept his eye completely around the horizon.

Having worked with him on my various visits to London for several years, having studied his cases before, during, and after operation, having repeatedly seen his hypothesis with reference to the existence of these causative factors in the production of chronic intestinal stasis verified upon the operating table, and having substantiated his findings in a large series of my own cases, I have tried to follow his example, and to sweep my own mental vision around the horizon rather than to fix my gaze upon this, that or the other particular point.

Therefore, with no possible desire to detract in the slightest degree from the brilliant work of your distinguished president, of Jonnesco and Juvara, of Douglas Reid, of Treves, and of the many others who, latterly, have contributed to the investigation of this interesting and important subject, I wish to emphasize what seems to me to be the logical point of view, that of considering all these intra-abdominal abnormal structures, whatever their origin and situation, as parts of the great whole, as possible factors in disturbing the body drainage in the production of chronic intestinal stasis.

For purposes of convenience of comparison I append brief descriptions of the various structures which come into consideration in connection with the bands described by Lane:—

1. *The Bloodless Fold of Treves.*[3] This fold is described by Reid[4] as follows: "Passing from the mesenteric border of the appendicular cecum and from the nonmesenteric border of the last part of the ileum to the posterior and lateral abdominal wall is a sheet of the peritoneum. This forms the anterior wall of a fossa completely closed save below. Its orifice is bounded in front by the free lower edge of the peritoneal sheet, medially by the ileum and the adhesions which bind this down, and posteriorly and laterally by the parietal peritoneum."

The fold of Treves passes over the caput coli and appendix, and, as Eastman[5] has pointed out, may adhere to the abdominal wall and resist for a time the completion of cecal torsion. Eastman suggests that the lower inner border of the bloodless fold of Treves may resist the drawing upward and inward of the last part of the ileum, thus preparing conditions favorable to the formation of Lane's kink, or actually causing it.

The Parieto-colic Peritoneal Fold of Jonnesco and Juvara.[6] In the majority of the cases this fetal fold arises from the peritoneum at the left or inner side of the ascending colon, passing over the anterior aspect of the ascending colon in an upward slanting direction. It is attached to the parietal peritoneum at the right of the ascending colon. It may adhere to the anterior and lateral aspects of the colon.

Practically the same relations as are presented by the parieto-colic fold or Jackson's membrane, when found in the adult, have been attributed by Reid[6] to the above-described fetal fold.

Several succeeding stages of the formation of Jonnesco's fold were found by Eastman,[6] indicating that adhesions may form between the serosa of the cecum and the mural serosa while the cecum is still sub-hepatic. The subsequent descent, with torsion or rolling inward upon the long axis, draws the parietal serosa over in front of the ascending colon in a slanting or spiral direction, like a ribbon wound spirally around a rolling cylinder.

"Jackson's Membrane." Jackson[7] describes this structure as follows "From a point just at the hepatic flexure to three inches above the caput coli there spreads from the parietal margin over the external lateral margin to the internal longitudinal muscle band, a thin vascular veil, in which long straight unbranching blood vessels course, most of which are parallel with each other and take a slightly spiral direction over the colon from the upper peritoneal attachment to the inner lower portion of the gut ending just above the caput. The appendix is not implicated in any way. Coursing with the blood vessels are numbers of shining narrow bands of connective tissue, which gradually broaden as they go and end in a slight fan-shaped attachment at various points on the anterior and inner surfaces of the colon. At these points of attachment the gut is held in rigid plication. At the beginning of the hepatic flexure the drawn membrane particularly angulates the contained colon."

The Genito-mesenteric Fold of Douglas Reid.[8] This fold of peritoneum, which is said to be rather common, passes from the mesentery of the terminal segment of the ileum down into the pelvis, being attached in the fetus to the genital gland below. It has, therefore, a secondary connection with the ileum and, through the peritoneum of the meso-appendix, with the appendix itself, under which it passes. This connection is perhaps responsible for the frequent association of appendicitis and oophoritis. Adhesions of the colon to the peritoneum of its own mesentery were also pointed out by Reid.

This genito-mesenteric fold is found in a surprisingly large percentage of fetuses after the seventh month, or even after birth at term, and Eastman[9] has found it in the adult.

"Attic Adhesions" (Morris),[10] "Anatomists have noted that web-like adhesions were found in the bile tract region so frequently that they seemed to be almost a normal characteristic of the region. We used to feel the same way about adhesions in the cecal region. Byron Robinson called attention to the fact that adhesions were

found in the bile tract region more frequently than elsewhere in the peritoneal cavity excepting in the pelvis in women; and that the cecal region stood third in order of abundance of adhesions." Peritoneal adhesions, according to Morris, are found to some degree in almost every adult on post-mortem examination. Those in the upper part of the abdomen he has aptly called "attic adhesions."

Origin of Intra-abdominal "Bands," "Folds," and "Veils." Three chief theories concerning the pathogenesis of the intra-abdominal structures under discussion have engaged the attention of the different investigators: (1) mechanical or evolutionary (Lane), (2) embryonic or congenital, (3) inflammatory and infectious. In addition to these, the combined congenital and acquired factors have been suggested as playing a part in the development of these structures as they are found in the adult.

Embryonic or Congenital Theory. In an early stage of fetal life the entire abdomen is filled with bands, resembling the conditions seen after an attack of peritonitis.[11] Toward the conclusion of fetal life these bands disappear and the adhesions melt away, although some may persist, as certain investigators have maintained. In order to determine how frequently such bands may persist and become factors in the production of chronic intestinal stasis or other abnormal condition involving the abdominal viscera, it will be necessary to examine carefully a large number of young infants as well as fetuses at various stages of development.

Chapple, in a recent personal communication, reports having dissected twenty-eight fetuses without finding any bands of the type associated with "Lane's kinks" and chronic intestinal stasis. Professor Keith, of the Royal College of Surgeons, London, examined in my presence last fall fifteen fetuses, in three of which he thought there was a rudimentary band that might be a factor in producing stasis. I must say that I was not convinced of this, as the bands were not at all similar to those found in the adult static individual. Eastman, and other investigators, have found a larger proportion of these prenatal structures which have been thought to persist, in some cases, in the adult, giving rise to some of the disturbances in which the gastro-intestinal tract is concerned. It is not within the scope of this paper to discuss the weight of evidence concerning the theories proposed to account for the existence, in the fetus, of these abnormal structures. More study is necessary before a conclusion can be reached.

Inflammatory and Infectious Theory. The inflammatory and infectious bands may be classed as, (1) endogenic—resulting from peritoneal reaction from infection within the colon, and (2) exogenic—resulting from infections transmitted from some inflamed organ in the immediate vicinity. Prolonged or repeated mild infections of the peritoneal covering of the cecum and appendix, transmitted through the intestinal wall, are considered by Pilcher[12] as a causative factor in the production of these membranous bands. Gerster[13] assumes a reaction of the peritoneum to infection and chronic inflammation of the colon, in the form of "characteristic vascularized transparent membranes (pseudo-peritoneum), which take their origin along the external lateral aspects of the cecum, ascending colon and hepatic flexure on one side, and the sigmoid flexure, descending colon, and splenic flexure on the other."

Inflammation, undoubtedly, plays a part in the formation of some forms of the membranous structures found within the abdominal cavity, and hence in the production of intestinal obstruction of one kind or another. It seems to me, however, that all these formations are to be distinguished from those which Lane describes as being of mechanical or evolutionary origin. For, as Lane has shown, these acquired bands, which he calls evolutionary, commence at a point most distant from the intestine, gradually approaching and securing the bowel. Inflammatory bands, on the other hand, commence at the point of attachment, progressing away from this.

Mechanical or Evolutionary Theory. Of the various theories proposed to account for the structures under discussion, that of Lane is, to my mind, the most plausible, accounting, as it does, for a much larger proportion of the cases than does either the embryonic or the inflammatory theory.

In a recent communication,[14] in discussing the influence of alimentary toxemia upon the bony structures, Lane laid down the following three laws as governing the changes which take place in consequence of the altered mechanical relationship of the individual to his surroundings:—

(1) "That pressure produces changes in the structure and form of the bones and in the form and function of existing joints, while it determines the formation of new joints."

(2) "That strain produces change in the form of the bones, and in the form and function of existing joints, and also produces new joints."

(3) "That when, apart from the exercise of pressure or strain, it is important, from the altered mechanical relationship of the individual to his surroundings, that a mechanism should be modified or an entirely new one developed, such a change takes place."

These same mechanical principles, according to Lane, govern the soft parts of the body and modify their structure. Following this line of reasoning, he has applied these laws to the abdominal cavity, and in this manner has accounted for the development of the various adventitious structures which he associates with chronic intestinal stasis in the majority of cases.

The membranous adhesions between the outer wall of the colon and the abdominal parietes, as well as in other segments of the intestinal tract, which were noted by Lane in cases of chronic intestinal stasis, were interpreted by him as newly

developed accessory ligaments, serving to counteract the tendency to enteroptosis incident to the disturbed mechanical relations of the bowel consequent upon the assumption by man of the upright position. In other words, the origin of these bands about the ascending colon, hepatic and splenic flexures, sigmoid, and other portions of the gastro-intestinal tract is referred by him to the mechanical factors of chronic constipation and the upright posture. He holds that nature attempts to relieve the strain of the persistent enteroptosis, and that the dragging of the displaced bowel is offset, as it were, through hypertrophy of its membranous supports—"the crystallizations of resistance," "the crystallization of lines of force,"—a physiological response to a mechanical demand, which conforms to the three laws as stated by him.

The mechanical relations of the large bowel are impaired primarily by the overloading of the large gut and of that portion which serves more especially as the cesspool of the gastro-intestinal tract, the cecum and the ascending colon. The excessive distention of this portion of the tract results very largely from the erect or sedentary posture of civilized man. While the cecum and ascending colon have great difficulty in passing on their contents in the erect posture, the evacuation of the cesspool is very much facilitated by the assumption of the supine position. Through the changed mechanical relations of the bowel, intestinal surfaces not normally in contact come into apposition, with the result that more adhesions form and interfere further with the passage of material through the lumen already constricted at the flexures. Obstruction of the appendix due to its acquired abnormal fixation, is a very common concomitant of the alteration in the form and mechanical relations of the cecum, and Lane directs attention to the relationship of so-called "appendicitis" to the overloading of the cesspool or cecum.

Lane has pointed out that obstruction in the drainage scheme may occur, in the first place, at points of normal fixation; that, in the second place, the intestine may become kinked by acquired bands, etc., " which formed in the first instance by nature, with the object of facilitating drainage, may have later come to cause very material obstruction." He has also directed attention to the various sites in the length of the alimentary tract at which this obstruction may occur, the points of predilection being: (1) in the third part of the duodenum, at the commencement of the jejunum; (2) at different points along the terminal coil of the ileum; (3) in the ileo-cecal region, including the appendix: (4) in the region of the hepatic flexure and the first part of the transverse colon; (5) at the splenic flexure; (6) at the sigmoid loop; (7) in the rectum.

These various changes involving the large bowel are admirably shown in Fig. 1 (Fig. 43, *op. cit.*, Lane, p. 84).[15]

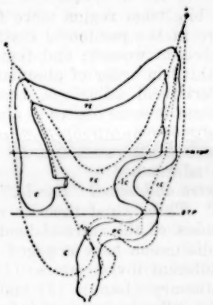

FIG. 1. Represents the several variations from the normal which the large bowel undergoes. The normal condition is shown as a firm outline, and the altered condition as a dotted outline. Note the prolapse of the cecum and transverse colon, the telescoping of the iliac colon and the elongation of the pelvic colon. (BTP) indicates the brim of the true pelvis. The hepatic and splenic flexures are drawn up and kinked by the development of acquired resistances shown by arrows.

I may say, in this connection, that in my own cases I have repeatedly verified many of Lane's findings, as I shall show upon the screen. It is often my practice, when operating upon patients whose condition has been shown, by the various diagnostic methods at our command, to be chronic intestinal stasis, to have an artist and a stenographer in the operating room. The artist, who is skilled in the recognition of anatomical conditions and the portrayal of these upon paper, sketches the conditions found in each case, taking accurate notes for purposes of identification. The stenographer notes the description of the condition and its treatment, as dictated by the operator. The finished drawings are then checked up by those who saw the operation. The pictures which I shall present, as verification upon the operating table of conditions portrayed by Lane in the diagrammatic sketches which I shall throw upon the screen, were made in the manner described. They have been selected from a large number merely as evidence of the existence of these bands, and as seeming to corroborate Lane's view with regard to the evolutionary nature of these structures.

"Jackson's Membrane" and Ileal Kink. Fig. II. (Fig. 32, *op. cit.*, Lane,[16] p. 25.) The tendency to displacement in the dilated cecum in a downward and inward direction is regarded by Lane as acting along the resultant of a parallelogram of forces. In order to oppose this tendency, resistances develop which correspond in position and action to the sides of the parallelogram. These lines of resistance, Lane maintains, "are crystallized first as bands, and later as distinct membranes, which as the outer limb of the parallelogram, connect the peritoneum lining the abdominal wall to the outer surface of the colon n its immediate vicinity. A larger area of abdominal peritoneum and of colon is gradually involved, and later still, as is the case in all

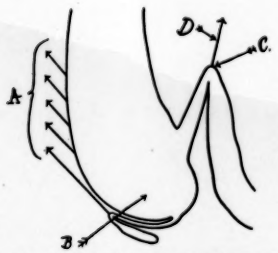

FIG. 2.—(A) Jackson's membrane, the lower part of which involves the appendix. (B) The distended loaded cecum. (C) Ileum kinked by band (D).

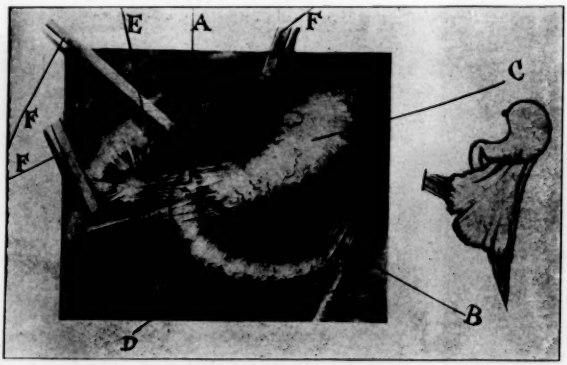

FIG. 4 *a*.—(A) Kinking at pyloric outlet. (B) Duodeno-jejunal kink. (C) Dilated stomach. (E) Bands to gall bladder. (F) Retractors holding up liver.

FIG. 4 *b*.—Another illustration of practically the same conditions shown in Fig. 4 *a*. Only more marked and loop of jejunum thrown to the right.

FIG. 5.—Normal curve of duodeno-jejunal junction.

FIG. 6.—Angulation of duodeno-jejunal junction produced by bands.

FIG. 7.—Nature's efforts, by the formation of bands, to prevent angulation.

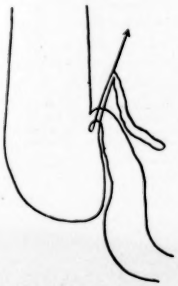

FIG. 8.—"Appendiceal Tie," with ileum kinked above by the appendix, and distended below.

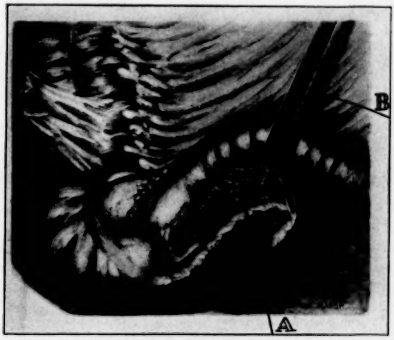

FIG. 8 a.—(A) Appendix caught up by band. (B) Retractor holding up ileum. When ileum is allowed to drop over appendix, the condition shown in Fig. 8 results.

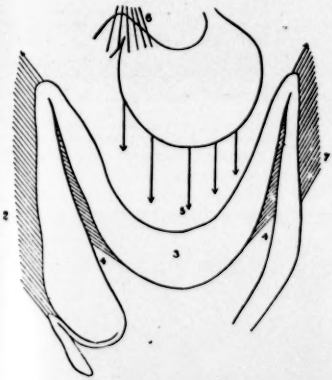

FIG 9.—(1) Represents the prolapsed cecum; (2 and 7) the crystallized resistances which tend to oppose the downward displacement of the large bowel and sustain some of the weight of the transverse colon transmitted through the crystallized resistances (4); (3) the transverse colon; (5) portion of the weight of the transverse colon transmitted through the great omentum to the convexity of the stomach; and (6) the acquired ligament that secures the duodenum and pylorus to the under-surface of the liver and gall-bladder.

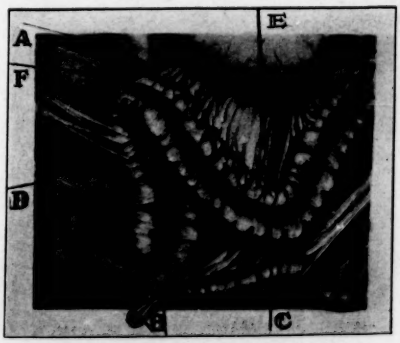

FIG. 9 a.—(From *B. M. J.*, Nov. 1, 1913.) also FIG. 2 b. (A) Dilated duodenum. Angulated duodeno-jejunal junction. (B) Lane's band and kink. (C) Prolapsed transverse colon. (D) Jackson's membrane. (E) "Portion of the weight of the transverse colon transmitted through the great omentum to the convexity of the stomach." (F) Acquired ligament securing duodenum and pylorus to under-surface of liver and gall-bladder.

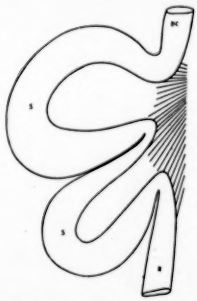

FIG. 10.—Fixation and obstruction of sigmoid.

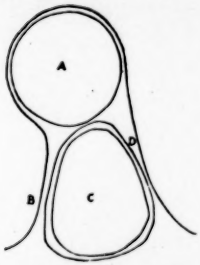

FIG. 12.—(A) represents the colon in transverse section; (B) the original mesentery; (C) the cystic ovary lying free in a cavity; and (D) the remains of the acquired adhesions.

FIG. 11.—Diverticulitis of sigmoid produced by approximation of two ends of loop of sigmoid.

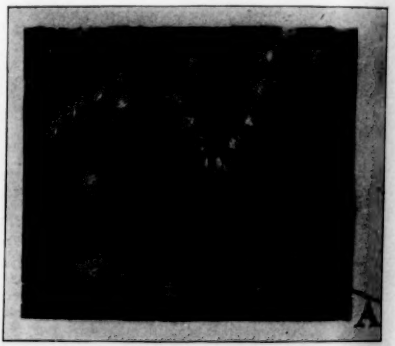

FIG. 12 *a*.—(From *Medical Record*, Sept. 27, 1913.) (A) Band in which stump of tube and ovary is caught.

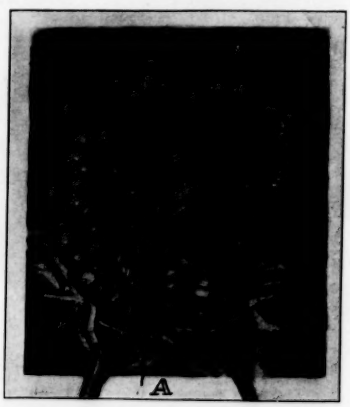

FIG. 11 *a*.—(From *Medical Record*, Sept. 27, 1913.) (A) Band Holding in approximation two ends of sigmoid loop, causing a diverticulum.

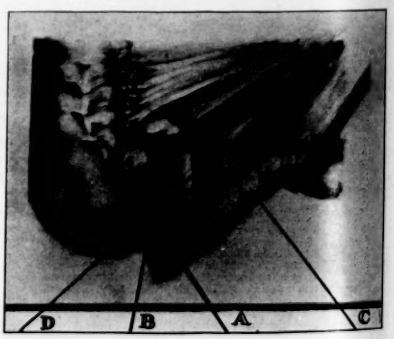

FIG. 13.—(A) Lane's band and kink. (B) Appendix caught behind. (C) Dilated and thickened ileum. (D) Collapsed and thinned ileum.

resistances which are crystallized in peritoneum, the bands are replaced by a layer of peritoneum which clings and tends to support the colon from the outside. As these bands and membranes develop, blood vessels form in them which later may become sufficiently large to require to be ligated if divided. This particular resistance when fully developed into a membrane, has recently been termed 'Jackson's membrane.'"

The distended loaded bowel is here shown dragging upon the resistances evolved to oppose its downward displacement into the true pelvis. The resistances external to the cecum are indicated by an arrow showing the general direction of the strain exerted by bands, adhesions, and omental structures. The lowest of these secures the appendix, which is kinked. The effects exerted upon the ileum at its point of fixation by the weight of the loaded cecum on the one side of it and by that of the obstructed loop of the ileum on its proximal aspect, are shown.

Fig. II-a, from my own series, represents Jackson's membrane and the ileal kink. Fig. II-b, which will be presented again,[17] shows the appendix caught back in the parieto-colic membrane, in a fashion similar to that portrayed diagrammatically in Fig. II.

The "crystallized resistances of peritoneum" are not limited to the cecum, but may extend up along the outer aspect of the ascending colon, even to the hepatic flexure, as we have already seen.

Ileal Bands. The inner limb of this parallelogram of forces is represented, according to Lane, at an early period by opaque streaks on the under surface of the mesentery, attaching the last few inches of the ileum, and commencing at its base at a point most distant from the bowel. The reason for this development he considers obvious: "Besides retaining the end of the ileum in position, the mesentery assists through the medium of the termination of the small intestine in holding up the cecum and in tending to oppose its downward displacement." "In its earliest development," he says, "as is the case with most conditions which evolve during the lifetime of an individual, because of a variation from the normal in the relationship to his environment, the effect of this acquired ligament or mesentery is useful and physiological, but later, when it kinks and obstructs the lumen of the ileum, it exerts a progressively deleterious effect on the well-being of the individual."

When this state of affairs develops, the inner limb of the parallelogram of forces, according to Lane, is represented by the portion of the ileum distal to the kink, "by the contracting acquired membrane which creeps around the circumference of the bowel, and by the posterior layer of the mesentery to which the membrane is attached. The upper layer of the mesentery presents no change, as abnormal strain is not exerted along it, but through the under layer only. In these circumstances the portion of the ileum between the cecum and the attachment of the acquired ligament is made to perform the function of a ligament very much more than is the case in the normal arrangement."

In Figs. III and IV (Figs. 36 and 37, *op. cit.*, Lane, p. 30), respectively, are diagrammatically indicated: (1) the normal condition of the stomach, small intestine, and cecum; (2) the several changes which result from ileal obstruction. The part of the ileum just beyond the kink in the ileo-cecal region becomes dilated and drags upon the duodeno-jejunal junction, at which point a crystallization of lines of force takes place, with resultant kinking. The duodenum, as a consequence of this obstruction to its drainage, becomes dilated, throwing an abnormal strain upon the lesser curvature in the neighborhood of the acquired suspensory ligament with which nature has endeavored to forestall trouble. This ligament becomes crystallized into a "resistance," and finally a kink takes place at the pyloric outlet. These conditions are indicated in Fig. IV-a and Fig. IV-b, of my series.

Duodeno-jejunal "Resistances" and Kink. Figs. V, VI, and VII (Figs. 39, 40 and 41, *op. cit.*, Lane, p. 80) are further illustrations of possible duodeno-jejunal conditions. Fig. V shows the manner in which the duodenum usually terminates vertically at the root of the transverse meso-colon, where it is continued into the jejunum as a gentle curve. Fig. VI represents the kinking and twisting at the duodeno-jejunal junction as the result of the strain exerted by the jejunum, and the consequent obstruction to the effluent from the duodenum. The resistances which, as peritoneal bands, are developed to oppose this drag upon the jejunum and the obstruction of the duodenal outlet, are represented by the arrows. These bands, it will be seen, run upwards from the commencement of the outer aspect of the jejunum to the peritoneum lining the adjacent abdominal wall. Fig. VII represents nature's efforts to ward off angulation at the duodeno-jejunal juncture by the development of "resistances crystallized in membrane," fixing the jejunal loop so as to avoid kinking. Fig. IV-a of my series, shows the angulation. I happen not to have in my series one to illustrate Fig. VII.

Lane has repeatedly emphasized the far-reaching effects of obstruction at the duodeno-jejunal junction. The distention of the duodenum, the dilatation of its lumen and hypertrophy of its wall, the infection of the contents with alien organisms, the lowering of the vitality of the gut by auto-intoxication, vascular enlargement, varying degrees of inflammation, ulceration, possible perforation, possible cicatrization, and stenosis of this portion of the bowel, are some of the phases of this condition. In consequence of infection of the duodenal contents, the pancreatic and common bile-ducts, which open into the duodenum, are infected, resulting, according to Lane, in more serious affections of the pancreas and the liver.

"Appendiceal Tie." In Fig. VIII (Fig. 38, *op. cit.*, Lane, p. 31) is represented diagrammatically the mechanism of the "appendiceal tie," or the "resistance" when it forms part of the inner limb of the parallelogram of forces. The cecum and ileal loops are both here shown to be distended with fecal contents, and as having fallen into the true pelvis. The end of the ileum is here shown as it hangs over the fixed portion of the appendix, which is secured by its acquired membrane or crystallized resistance (indicated by the arrow). The lumen of the ileum is thus diminished by this fixed portion of the appendix. The greater the drop of the cecum, as it pivots on the fixed appendix, and the greater the dropping and distention of the ileum, the more complete does the obstruction by the appendiceal tie become. This, I think, is perfectly apparent.

In Fig. VIII-a, from my series, the appendix is caught up in such manner that when the ileum is not held up, as it is shown in the picture, it drops over the appendix, and becomes kinked in the manner shown in Fig. VIII.

"Resistances" Which Involve Pancreas, Liver, Stomach and Large Intestine. Fig. IX (Fig. 42, *op. cit.*, Lane, p. 35) represents the mechanism whereby the pancreas, liver, stomach and large intestine, as well as the small intestine, are involved in the development and crystallization of lines of resistance. In this diagram 1 represents the prolapsed cecum; 2 and 7, the crystallized resistances which tend to oppose the downward displacement of the large bowel and sustain some of the weight of the transverse colon transmitted through the crystallized resistances, represented by 4; 3, the transverse colon, prolapsed; 5, portion of the weight of the transverse colon transmitted through the great omentum to the convexity of the stomach; 6, the acquired ligament that secures the duodenum and pylorus to the under surface of the liver and gall-bladder.

Fig. IX-a, of my series, represents these conditions.

Fixation and Obstruction of Sigmoid. Figs X and XI (Figs. 46 and 47, *op. cit.*, Lane, pp. 41 and 43, respectively) represent (1) fixation of the sigmoid loop, and (2) the production of volvulus by the approximation of the ends of the loop, by means of acquired adhesions.

Fig. XI-a, from my series, is an excellent illustration of the condition represented in Fig. XI.

The "Last Kink." The "last kink," which affects the large bowel where it crosses the brim of the true pelvis on the left side, is represented in cross section by Fig. XII (Fig. 48, *op. cit.*, Lane, p. 92). Lane attaches great importance to this obstruction, which develops early in life. The bands which cause this obstruction form on the outer surface of the mesentery of this part of the large bowel, and are, in his opinion, like all other acquired mesenteries and adhesions, the crystallization of lines of resistance to downward displacement. The ovary and Fallopian tube are often involved in these adhesions.

Fig. XII-a, of my series (from *Medical Record*, Sept. 27, 1913), shows adhesions between the stump of the ovary and tube and the sigmoid. The ovary had been caught in the adhesions, and had been removed before I saw the case. The adhesions re-formed about the stump, as shown in the picture.

Fig. XIII represents the findings in a case of marked chronic intestinal stasis, operated upon by Sir Arbuthnot Lane, the writer assisting, at the New York Polyclinic Hospital, Nov. 28, 1913. It shows a small "Lane's band," an ileal kink, the appendix caught up behind, a dilated ileum with much thickened wall, and the collapsed part of the ileum with thinned wall. At operation a non-vascular band was found angulating the terminal ileum and binding it down deeply in the pelvis. General visceroptosis. Duodenum dilated, extending almost into the true pelvis. Marked secondary evidence of static condition in other organs. Note the absence of Jackson's membrane and other bands.

From this categorical summary of Lane's exposition of the changes which take place, within the abdomen, in consequence of the altered relations brought about by the assumption of the upright posture, it seems to me that he makes out a very good case for his mechanical or evolutionary theory of the origin of all the adventitious structures which, in his opinion, play so important a part in the production of chronic intestinal stasis. It may be said, however, that much work needs yet to be done before any theory can be firmly established. We are only beginning to explore the field which he has opened to us. The establishment of the existence of these various structures takes us a long way. We have yet to determine more about their origin, and to follow the leads which he has given us with reference to the far-reaching effects of the conditions brought about by the development of these structures. The field, it seems to me, is one of the most alluring and promising which modern medicine and surgery present. It is certainly rich in promise for the many who, otherwise, would be doomed to more or less complete chronic invalidism.

THE PROGNOSIS OF SARCOMA OF THE TESTICLE.

BY E. A. CODMAN, M.D., BOSTON,

AND

RUSSELL F. SHELDON, M.D. BOSTON.

IT sometimes requires a personal interest to stimulate a real effort to find out the facts about a given surgical problem. Recently we operated on a case of sarcoma of the testicle and it happened that "the case" was an intimate friend of one of the writers. We had seen the tumor when it was quite small and had made a diagnosis of tuberculous epididymitis. This diagnosis was based on the fact that apparently the epididymis was involved and not the testicle proper, and that small nodules were present in the other epididymis and in one of the seminal vesicles. It was further substantiated by the presence of a quiescent tuberculous focus in the apex of one lung. Two prominent genito-urinary specialists confirmed the diagnosis and two tuberculosis specialists accepted the diagnosis without question.

These facts are mentioned because our further investigations showed that similar mistakes occasionally occur and that the reason is that the text-books usually state that sarcoma does not begin in the epididymis. We have found cases which show that this is not a fact.

Eventually the testicle was removed—nine months after the lesion was first noticed and when the tumor was the size of a small lemon. Fortunately we had begun to suspect sarcoma, and removed the entire contents of the scrotum from the internal ring down, without attempting exploration, which might have spread the disease. On section the epididymis and testicle were almost wholly replaced by the growth, a portion only of the testicle being compressed to one side. Nevertheless, the disease had not passed the tunica albuginea anywhere and was perfectly encapsulated.

Therefore on the whole the conditions were more favorable than usual, for it was fairly early, no obvious metastasis or local extension had taken place, and neither tapping nor exploration had been given their opportunity to spread the disease.

What are the chances for this patient?

Here is what prominent text-books say in regard to the matter. Watson and Cunningham say: "The operation to be of any value and to offer any hope of cure must be done early and must include the cord, the inguinal lymph nodes and also the deeper abdominal chain." Bevan in Keen's Surgery says: "The prognosis is bad. I have never seen a permanent cure, even after fairly early and complete castration." Bonney gives the most hopeful statement in regard to our patient. He says: "It is only when the tumor is still confined within the tunica albuginea that there is any hope of cure." Guiteras remarks vaguely but probably truly that the "prognosis depends almost entirely on the presence or absence of metastatic involvement of the abdominal glands." Greene-Brooks offers slightly more hope in saying that "early removal generally warrants a better prognosis than in most cases of sarcoma elsewhere."

In regard to origin, Watson and Cunningham say that the disease rarely begins in the epididymis. From other authors we gather little information that this is even a possibility. In all the books the classical differentiation is between tuberculous epididymitis, syphilis, and tumor.

A search of recent journal literature led us to two articles—real contributions, not advertisements. These were enlightening. Chevassu, after extensive pathologic study, became clinical and really looked up some cases to find out what did happen. In the first place he simplified the classification which had been so mysterious and confusing in the text-books, and practically reduced all tumors of the testicle to two,—the seminoma and the mixed tumor. Using these clinical classifications he gives us the results of his researches as follows:

Number of cases	100
Living four years after castration	19
Dead	81

That is, 19% of his cases were cured by castration. Of the 19 cured, 16 showed pathologically "epithelioma seminal," but only 3 were of the "mixed" type. He cites two cases in which additional dissection was done and the abdominal glands showing metastatic involvement, removed. He, therefore, demonstrated the practicability of the operation, but sufficient time had not elapsed to prove a complete cure. The greater the variation in tissue, the worse the prognosis. This certainly looks more hopeful for our patient, who is distinctly in the seminoma class.

The second article was by Ewing of New York, pathologist to Columbia.

This paper is a pathologic one and in brief reduces the pathologic classification still further, for in the end he shows us that all these testicular tumors, sarcomas, adenocarcinomas, teratomas, and all the wordy changes which have been rung on similar terms amount to this: That one and all are derived from the spermatic cells and like the cells themselves have

all possibilities of development short of a complete fetus.

Almost every tissue known in the body has been found in a testicular tumor—even a nearly perfect uterus. Thyroid glands, perfect teeth, bone, cartilage, etc., have been demonstrated; often several tissues in the same case. Usually, however, the epithelioid elements outgrow all the others and we have a simple large round-celled tumor, which one pathologist classes as sarcoma because it arises from a mesoblastic organ, and another calls alveolar carcinoma because of its cellular arrangement and appearances. Practically all testicular tumors contain some of this tissue, though sometimes it is outgrown by the teratomatous elements. When pure it is the common tumor which we call sarcoma or carcinoma and Chevassu calls seminoma.

We have undertaken to look up the cases operated on at the Massachusetts General Hospital in the last forty years to see whether our facts fit those of Chevassu.

Owing to the varied character of the nomenclature of the pathologic reports of our cases we have considered it best not to endeavor to separate the different forms and we simply accept the view of Ewing that all testicular new growths are essentially the same. During this period we find 80 cases, classified chiefly as sarcoma or carcinoma of the testicle. Sixty-three have reports of pathologic examination of the specimens removed at operation. In the cases of those without reports the clinical diagnosis was sarcoma or carcinoma.

Of the 80 cases we are unable to procure the end results of 16. It is hardly fair to suppose that all of these have died, since in the case of at least four of them registered mail has not been returned to the writers after over a month's interval.

Of the 64 known cases we can present the following figures:

Living and well	13
All operated.	
Dead from other causes	12
10 operated.	
Dead from disease	39
33 operated.	

This gives the mortality from the disease 61.9%. Excluding those not operated, in which the condition of the testicle was manifestly inoperable, or else discovered at autopsy in deaths from entirely different diseases, the mortality is reduced to 58.93%.

This is of course a large figure; but is it not much smaller than we have been taught to believe? Thus out of 56 cases operated, we find that 13 are living (average time after operation 9 yrs.; extremes 2 and 28 yrs.), and that 10 have died from something else (average time after operation, 10 years; extremes, 7 months and 26 years). That is, 23 or 41.07% of those operated survived the disease. If 8 unoperated cases and 12 cases operated on when metastases were evident are excluded, we find that 52.27% were cured. We must conclude, therefore, that the prognosis of sarcoma of the testicle, while bad, is not, when operated, so universally bad as text-books would lead us to infer. We, therefore, believe that the prognosis of our case is better than even.

Among our 64 known cases we find but one with the origin of the disease in the epididymis, but among the 16 the results of which were not traced, there are two of this nature. In these three cases the preliminary diagnosis was tuberculous epididymitis; in two the pathologic report was sarcoma; in the third there is no record of pathologic examination, but macroscopically the specimen was sarcoma. Ewing also has seen cases where the tumor arose in the epididymis.

We find that in 4 of the 64 known cases the testicle had not descended at birth, thereby confirming Odiome and Simmons in the belief that the undescended testicle is more prone to sarcomatous degeneration than the normally placed organ.

Let us show the figures in tabular form:

Living and well, 13.
Age, 24 to 57 years. Average 42 years, 9 months.
Pathology—Simple tumors, 12. No report, 1.
Duration of symptoms before operation, 5 months to 5 years. Average 20 months.
Period elapsed since operation, 2 to 28 years. Average 9 years.
Tapped, 3.

The only operation done was orchidectomy

Died from other causes, 12.
Age, 24 to 68 years. Average 49.
Operated, 10.
Simple tumors, 5.
No report, 7.
Duration of symptoms before operation, 2 weeks to 2 years. Average 7 months.
Period elapsed since operation, 7 months to 26 years. Average 10 years.
Tapped, 2.

NOTE: The two cases not operated: one death from diabetes, the other from chronic nephritis with uremia. Autopsies on both.

In the case surviving but seven months after operation the patient was burned to death. The next case in point of time survived three years, death being due to injuries received in a fall. The remaining cases all survived over five years.

Died from disease, 39.
Operated, 33.
Pathologic report—Simple tumors, 34 (1 autopsy).
Age, 5 to 65 years. Average 37.
Metastases—Evident, operated 2, not operated 10; not evident 21.
Tapped, 6.
Duration of symptoms before operation, 2 months to 6 years. Average 15 months.
Duration of life after operation, 3 days to 3 years. Average 10.3 months.

NOTE: There is one more report than operation since one case had autopsy in the hospital.

The significant points we think are as follows: Of the 33 operated cases which died from the disease, 21 had no sign of metastasis at operation, yet death occurred in all within three years. Only 12 showed metastasis at operation; in spite of the fact that in 2 of these additional dissection was done, all were fatal.

Our figures confirm those of Chevassu, which show that a patient is safe after the three-year limit.

On theoretical grounds we believed that tapping in these cases was contraindicated in that new paths for lymphatic infection might be opened up. From our statistics, however, we do not find this hypothesis to be borne out by the facts, nevertheless we think it is a procedure to be avoided.

Nearly every case gave a history of trauma; but we are not inclined to regard this as important in the etiology.

In two of the cases in the group of "Dead from Other causes" we find skin ulceration at time of operation. We therefore take exception to the statements about the hopelessness of those cases with extension beyond the tunica albuginea. One of these had a pathologic report of sarcoma, but in the other there was no report.

The radical operation, as advised by Watson and Cunningham and Chevassu, has not been done at the Massachusetts General Hospital. Whether had this been attempted, some of the 21 cases who died within three years in spite of no evident metastasis at time of operation, might have lived, is, of course, a question. In our case, in which the growth was still confined within the tunica albuginea, no further operation was done; but had the growth penetrated this structure, we believe further dissection would have been justified.

From 21 cases in which the location of metastases is mentioned, we find the following facts:

In abdomen alone	13
" abdomen and lung	1
" neck and liver	1
" axillae and abdomen	1
" lungs	1
" spinal cord	1

The great majority, therefore, show abdominal metastasis, and might be helped by a removal of the retroperitoneal glands.

Dec. 23, 1913. One patient has no sign of recurrence at present date. Operation Jan. 15. 1913.

HAVE THE EARLY CLAIMS OF SALVARSAN BEEN REALIZED?*

BY C. MORTON SMITH, M.D., BOSTON.

THE extravagant claims which were made for salvarsan, on its introduction into the small group of specific remedies, are well known. To what extent are these claims being realized?

Organic arsenical compounds had been used at various times in the treatment of syphilis and skin diseases, as well as sleeping sickness. Some of the preparations were found to be dangerous, notably atoxyl, the use of which was frequently followed by total blindness due to a primary optic atrophy. With these results fresh in mind many cautioned against the use of arsenobenzol lest it, too, should prove to be neurotrophic.

In the light of experience with salvarsan, and its later modification, neosalvarsan, is there any real danger to the cranial nerves, and what are the contra-indications? My personal experience covers 37 months, during which time I have had to do with between 3000 and 3500 injections, all of which, with the exception of a very few at the outset, have been given intravenously.

Salvarsan should be administered as soon as a positive diagnosis can be made. In lesions uncomplicated by pus organisms, it is often possible to demonstrate spirochaetes very early with the dark stage microscope or the India ink method; it is more uncertain with stained specimens. Failing to find the organisms, the Wassermann test is usually positive by the end of the fourth or fifth week, sometimes earlier. Salvarsan injected before the appearance of secondary eruptions prevents or retards their occurrence. It is during the primary and early secondary stage that we believe the disease most curable. I have seen a small number of apparent cures follow a single injection of salvarsan, but we no longer expect this, therefore the injection is repeated in five to ten days and again in two or three weeks, and afterward as the case demands; usually from four to eight injections of salvarsan are given. Mercury, preferably by intramuscular injection, should be used to supplement the salvarsan, and the effect of treatment measured by the Wassermann reaction.

There is no doubt as to the value of such intensive treatment, and when given during the primary or early secondary stage, a negative Wassermann should be possible at the end of six to nine months, after which blood tests should be made two or three times a year for the next few years, resuming treatment should the test become positive. Many cases so treated still show negative tests.

When, for any reason, the treatment is delayed beyond the primary stage, it is more diffi-

* Read at a meeting of the New England Otological and Laryngological Society, Massachusetts General Hospital, Nov. 18, 1913.

cult to bring about a speedy serologic change. This is probably due to the fact that the germs are widely disseminated; have become more or less encapsulated, or walled off, by inflammatory products, and are not reached by the remedy. Iodide of potash is of value in such cases on account of its absorptive action on these inflammatory products, not being an active spirillicide.

It is the opinion of most syphilographers that mercury has not been displaced and that a combination of salvarsan and mercury in the treatment of syphilis is more effective than either alone. Wechselmann, on the contrary, cautions against this and is inclined to attribute some of the accidents that have occurred to this combined method.

In general the early manifestations of syphilis are a menace to the community, while the late lesions are dangerous to the individual from damage to the nervous or circulatory system. Primary and secondary lesions heal promptly under salvarsan, and as these are the common sources of infection much is done in preventing contagion. Chronic papular eruptions of palms and soles are especially resistant to mercurial treatment. These yield promptly to salvarsan. This drug is also more active than mercury in changing the Wassermann reaction from positive to negative. We know that many cases considered cured with mercury and thought to be immune, now give positive blood tests, showing they are still syphilitic. We believe the use of salvarsan materially shortens the course of treatment, thereby making possible an earlier marriage and healthy children.

Desirous of improving his invention, Ehrlich continued his experiments and the 914th combination is sold under the name of neosalvarsan. It is supposed to be less toxic and makes a neutral solution ready for use by simply dissolving in sterile water at room temperature and is said to oxidize quicker than the old preparation. It is much less irritating to the tissues in case of extravasation and has no apparent effect on the lining of the veins. The same vein can be injected over and over, which was not always possible with the old preparation. It requires .9 gm. of neosalvarsan to equal .6 gm. of salvarsan. On account of the greater ease of preparation, neo possesses a distinct advantage. Moreover, patients are less likely to have reaction following the injection, and when it does occur is usually several hours later than with salvarsan.

Is there any material difference in the therapeutic effect of the two preparations? Fordyce thinks neosalvarsan less efficient than an equivalent dose of salvarsan and also that it is more likely to produce skin eruptions. The latter has not been our experience. Ravogli believes one injection of salvarsan equal to two or three injections of neosalvarsan. He has also seen fewer toxic symptoms after its use. This is not in accord with general opinion. Howard Fox considers the symptomatic action of neosalvarsan is slightly less than salvarsan, while its serologic action is considerably less than the older preparation. However, it is not as disturbing to the vein. Trimble, after careful observation of 300 cases, failed to see much difference in the effect of the two remedies, and the simpler technic and less irritating qualities of the neosalvarsan make it superior to the older preparation. I am inclined to coincide with Trimble's conclusion.

Whitehouse found that in all cases of syphilis of the skin or mucous membrane, whether primary, secondary or tertiary, the lesions healed as promptly and surely after neo as after salvarsan. With this I am in perfect accord. Serologically he found both more effective in primary and secondary than in tertiary cases. However, he obtained 20% more permanently negative Wassermanns from the use of salvarsan. None of these cases received combined treatment with mercury. Schamberg has used an intra-gluteal injection of .1 gm. salvarsan or .15 gm. neo weekly to supplement intravenous injections of salvarsan or intramuscular injections of gray oil. The salvarsan is suspended in 1 or 1½ c.c. of sterilized petroleum oil with a half minim of beechwood creosote. This can be put up in ampules and used like gray oil.

Salvarsan is responsible for a relatively small number of deaths. Some of the fatalities occurring after its use should not be charged to it. I refer to cases where the drug was employed as a last resort, the patient being past all reasonable chance of help and dying in spite of the drug—not on account of it. In April, 1913, Finger stated that 142 deaths had been reported. At autopsy many of the fatal cases have shown a hemorrhagic encephalitis, acute nephritis or enteritis causing death within a few days. Finger also cites 34 cases of encephalitis, of which 9 recovered. He states that these cases are due to the toxic action of salvarsan as confirmed by experimental research. When one considers the vast number of injections that have been given during the past three and a half years, many by men who have been syphilographers only during that same period, the wonder is that fatalities have been so few. With ordinary care in selecting cases the administration of salvarsan should carry about the same or less risk than chloroform anesthesia. There have been no deaths from the drug among our patients, nor have I seen a reaction I would not endure were I in the same condition. A very few patients have felt faint or experienced a sense of discomfort about the chest during the injection, symptoms suggesting mild anaphylaxis. These manifestations have lasted from a few seconds to a few minutes. In no case which showed these symptoms was there a possibility of the introduction of air. A neurotic young woman, syphilitic ten years, had received two intravenous injections of salvarsan with no particular reaction; when about half through the third injection she complained of smarting of her right eye and thought the nurse had held smelling salts too near. Soon there

was evident edema, first of the under, then the upper lid and conjunctiva, followed by the same condition in the left eye; and chemosis became so great as to entirely cover the iris. Dr. Quackenboss saw her at the time and found no changes in the fundus. The swelling disappeared under cold compresses and was evidently a neurotic edema.

Reactions are more frequent in nervously sensitive persons, patients in the florid stage and those who have not taken mercury. Occasionally transient erythematous rashes occur upon the skin, probably of arsenical origin. Existing syphilitic eruptions not infrequently become brighter soon after an injection of salvarsan. This is the so-called Herxheimer reaction and occurs most often in florid cases, supposed to be due to the slaughter of large numbers of spirochetes and consequent rapid liberation of endo-toxines. Chills, fever, nausea, vomiting, diarrhea, etc., that sometimes follow the injection have been laid to the use of aged water in preparing the solution. We use only water both freshly distilled and sterilized, but still see an occasional reaction. Last year we kept sterile saline solution at room temperature from March to December, and Dr. Bell of Prof. Folin's laboratory reported neither bacterial nor chemical change.

The early contra-indications were heart and kidney disease, optic atrophy and general weakness. We have given salvarsan in valvular heart disease many times, modifying the dose to suit the patient. There have been a number of cases of syphilitic aortitis and myocarditis treated, with no untoward results and some have shown a decided improvement. A nephritis, unless it be of syphilitic origin, should still be looked upon as a contra-indication. Corlett has recorded a case of acute arsenic poisoning which he ascribes to faulty elimination. The patient showed nothing after the first injection of .6 gm. The following week he received .9 gm, and three days later returned with typical symptoms of arsenical poisoning and subsequently had paralysis of the bladder, rectum and lower extremities lasting four months. The patient's weight is not given. It is our practice to graduate the dose according to weight.

What are the dangers to the cranial nerves?

For a year and a half we have had a routine examination of the eyes of all patients at the Dispensary before the administration of salvarsan and a record kept of refractive errors and fundus changes. From July 1, 1912, to July 1, 1913, 606 injections were given and 4 cases showed the same subsequent changes, *i.e.* vitrious opacities and a neuro-retino-choroiditis. In these cases only one eye was affected, whereas after atoxyl both were involved, and total blindness followed a second injection, while our cases that have received subsequent salvarsan treatment promptly, have improved without exception. Dr. McAdams, who has examined many of the cases for us is convinced the changes were due to the disease and not to arsenic. Furthermore, since the treatment has been more energetic none of these accidents have occurred. Fordyce has lost all fear of salvarsan having any predilection for the optic nerve. Moreover, he has used the drug in several cases of optic neuritis with benefit. We have had the same result. He cites a case of advanced optic atrophy where ten injections of salvarsan had been given with marked improvement in vision and enlargement of the visual field. We, also, have given the drug in a few cases of optic atrophy with no untoward results.

Ruggles reports a girl of 22 with almost complete loss of vision in both eyes following iritis and optic neuritis. Her sight became normal after the fourth injection of salvarsan.

In talking with several ophthalmologists I have yet to learn of a single instance where salvarsan has caused trouble with the optic nerve.

In regard to the auditory nerve, Fordyce states that no cases of auditory neuritis have occurred in his practice, but he has seen several cases of involvement of the auditory apparatus in secondary syphilis where no salvarsan had been given. Ravogli has seen two cases of deafness, both of which he believed due to the disease and not to the treatment. At the dispensary we have had no routine examination of the ears. That sudden deafness due to syphilis occasionally occurs during the secondary stage of the disease was well known before the advent of salvarsan. In 1897 Dr. E. A. Crockett of this society collected and reported between fifteen and twenty cases of this character, one of which came on without treatment and one while under energetic mercurial and iodide treatment, deafness being due to a specific labyrinthitis. Two of the cases he reported occurred in my practice. Both were early secondary cases and both recovered practically normal hearing under pilocarpine and energetic mercurial treatment. The onset was sudden and total deafness followed, rapidly accompanied by tinnitus, virtigo, and temporary facial paralysis.

The symptoms and conditions are almost identical with the cases that have occurred after salvarsan. During the past three years I have seen three cases of deafness, two in my own practice and one a patient of Dr. Post. One of my patients does not properly belong in this group, as his disease was contracted in 1905 or 1906. His last 606 was in November, 1912. Wassermann Test was negative in February and again just before his deafness came on in April of this year. He now tells us of getting an electric shock from a telephone receiver a day or two before the deafness came on. His hearing is gradually improving. The Wassermann test in October, 1913, was still negative. The other two cases occurred within six months of infection. One remained unilateral, the other came first in one ear, then in the other. Both had a labyrinthitis and both a temporary facial paralysis. I believe now that both should have received en-

ergetic salvarsan treatment at once. Dr. Post's patient had one injection of salvarsan, while mine had two injections of neosalvarsan a month apart. There have been other cases in this city of the same sort, undoubtedly due to the disease. It is the general belief that the neuro-recurrences or nervous relapses are due to the syphilitic process in a very large proportion of the cases,—if not all.

However, Finger believes some are due to arsenical polyneuritis. He claims the tardy neuro-recurrences have an incubation period of two or three months and occur almost invariably in patients who have been treated with salvarsan at the end of the primary or early in the secondary period, when the system is flooded with spirochetes. He thinks it plausible to assume that the spirochaetes are then leading a saprophytic existence on the meninges and doing no harm until the toxic action of salvarsan is felt, especially on the capillaries. With normal resistance thus reduced, the spirochaetes can exert their malign influence on the tissues. Insufficient treatment thus favors the neuro-recurrences, but energetic combined treatment may not absolutely prevent them.

It is claimed that arsenic from intravenous injections is not found in the cerebro-spinal fluid, therefore it cannot be relied upon to accomplish as much in syphilis of the brain and cord as intra-spinous injections, according to the experience of Flexner in his work on meningitis. Salvarsan, even in weak solutions, cannot be injected into the canal. The work of Noguchi in demonstrating spirochaetes in the brain tissue of paretics and the successful inoculation of rabbits with the cerebro-spinal fluid from tabetics, shows conclusively that to be effective the spirillicide must reach the spinal canal. Work has been going on along this line for some time, using the salvarsanized serum injected into the canal; usually the patient's own serum is utilized. Improvement, both as regards clinical symptoms and laboratory tests, have generally, or often, followed the employment of this method. Whether it will be possible permanently to arrest the progress of syphilitic disease of the nervous system by this means, time alone will tell.

Conclusions:—

1. The early hope of curing syphilis with a single massive injection of salvarsan has not been realized.

2. It is a potent remedy in healing all manifestations on the skin or mucous membranes.

3. It is more efficacious than mercury in changing a positive to a negative Wassermann reaction.

4. Its prompt action on early moist lesions has a decided effect in limiting the spread of contagion.

5. The early fears of damage to the cranial nerves appear to be groundless.

6. When given in proper amounts at proper intervals it is practically devoid of danger.

Clinical Department.

A CASE OF STRANGULATED RETRO-PERITONEAL HERNIA OF THE SMALL INTESTINE INTO THE PARA-DUODENAL FOSSA.

BY LINCOLN DAVIS, M.D., BOSTON,

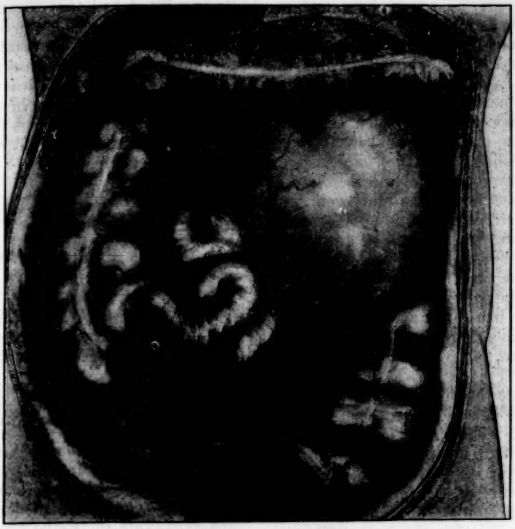
Assistant Visiting Surgeon, Massachusetts General Hospital.

ABOUT midnight of July 14, 1913, I saw, in consultation with Dr. M. Sturnick of Dorchester, a man presenting the symptoms of acute intestinal obstruction. The provisional diagnosis of volvulus was made, and he was recommended for immediate admission to the Massachusetts General Hospital. He entered the accident department of the hospital at 2.40 a. m., July 15, 1913, Hospital No. 190151. The following history is taken largely from the hospital records:

B. V. Age 48. Married. Born in Russia. Tinsmith. Entered Massachusetts General Hospital, July 15, 1913, at 2.40 A. M.

P. H. Has always been well except for one attack six years ago of acute abdominal pain with vomiting, lasting six days. Has been troubled with gas in stomach and discomfort two to three hours after eating, since then. Relieved by soda bicarbonate. Bowels regular. Micturition normal.

P. I. At 3 P. M. yesterday began to have pain in region of umbilicus. Had eaten canned salmon two hours before, and thought it indigestible. Pain severe at onset but soon became less severe for a short time. Vomited several times. Bowels moved normally yesterday morning. Small loose movement one and a half hours after onset of attack. For last few hours pain has increased in severity and become continuous. No result from low enemata. Morphia and atropin given by patient's physician. Temperature 97.6. Pulse 88. Respiration 22.



P. E. Well-developed and nourished man in considerable pain. Pupils normal. No adenopathy. Throat negative. Tongue, moist white coat. Heart and lungs nothing abnormal made out.

Abdomen full, markedly distended and tense, loud tympany throughout. No dullness or signs of fluid. Board-like rigidity of whole left side of abdomen. Spasm somewhat less on right. Moderate general tenderness, most marked to left of umbilicus. Pressure on left side of umbilicus causes pain referred to region of umbilicus. No costovertebral tenderness.

Rectal Examination. Rectum balooned. No tenderness. Extremities and reflexes normal. No herniae. Leucocyte count, 20,500.

Patient sent to ward, and given high M. G. W. enema without result. Patient's condition at this time became rapidly worse and operation was decided upon without further delay.

Operation. Four-inch median abdominal incision below umbilicus, discloses bulging retroperitoneal tumor, size of a football lying mostly to the left of the median line, extending into flank and up to epi-

gastrium. Transverse colon passed across upper portion of mass. Incision enlarged above umbilicus. Parietal peritoneum incised with escape of considerable turbid, bloody fluid. Trocar was then inserted, entered a loop of bowel, drawing off a little gas. The incision in the posterior parietal peritoneum was then enlarged and a large mass of distended, plum-colored small intestine delivered. Trocar wound in intestine closed with double layer of linen sutures. After a puzzling search, the point where the ileum emerged from the retroperitoneal pouch was found. This was close to the point where the duodenum emerges from under the mesocolon (fossa duodeno-jejunalis) leading to left. Large vessels passed over this opening, probably inferior mesenteric vein. The bowel was found adherent to the edge of the opening, these adhesions were freed. At this point the bowel wall was thickened, deep red in color, but distinctly viable. This part of the bowel was about one to two feet from the ileocecal valve. This short distal portion was collapsed and empty. All the remainder of the ileum and the entire jejunum lay in the hernia sac. With considerable difficulty, inch by inch, the herniated intestine was pulled through the opening, the last portion being difficult on account of distention. The hernial ring could not be enlarged on account of large mesenteric vessels which ran close to its edge. No attempt made to close hernial opening on account of alarming condition of patient. Intestine pressed back into peritoneal cavity with difficulty and abdominal wall closed with through-and-through sutures of s. w. g. Dry dressing. Skultitis. Patient to Ward D. in poor condition.

Patient failed to respond to stimulation and died at 9.10 A. M. No autopsy.

The above case, on account of its rarity and very serious import, is worthy of record.

Moynihan has published a monograph on the subject of retroperitoneal hernia, giving a very complete history of the subject, with full reference to the literature. He describes nine fossae in relation to the duodenum.

1. Superior Duodenal Fossa.
2. Inferior Duodenal Fossa (Fossa of Treitz).
3. Para-duodenal Fossa (Fossa of Landzert).
4. Mesenterico-parietal Fossa (Fossa of Waldeyer).
5. Mesocolic Fossa.
6. Posterior Duodenal Fossa.
7. Duodeno-jejunal Fossa.
8. Inter-mesocolic Fossa.
9. Infra-duodenal Fossa.

The first five are the commoner fossae, the last four being very unusual.

As to the origin of folds and fossae, Moynihan sustains the view of Treitz, that they are traction folds, the result of dragging of the intestines in the developmental change of position.

In this case the fossa involved seems to correspond to the description of the para-duodenal fossa, or fossa of Landzert. The opening of this fossa is bounded in front by the plica venosa, which consists of the inferior mesenteric vein arching over to join the splenic vein. It is usually accompanied by the left colic artery. The accompanying illustration is a diagrammatic representation of the appearance of the mass upon opening the abdominal cavity.

Moynihan records 65 cases of left duodenal hernia and 17 cases of right duodenal hernia. These herniae are found at all periods of life, the youngest is that of a case recorded by Brösieke, in which the patient was fourteen days

old. Moynihan concludes that the hernia is often congenital.

Under favorable circumstances it is possible to make a probable diagnosis during life. Leichtenstern says: "The circumscribed globular distention of the mesogastrium with retraction of the region corresponding to the colon; the firm, elastic, spherical lump which can be distinctly felt when the abdominal wall is thin, giving the impression of a large, somewhat movable cyst and extending from the mesogastrium to the left; the peculiarity that this well defined tumor always yields a sonorous note on percussion and clear intestinal sounds on auscultation, also the presence of hemorrhoids and the loss of blood from the rectum in consequence of the compression of the inferior mesenteric vein, permit, when taken in connection with the subjective troubles indicating chronic disease of the abdominal organs, a probable diagnosis to be made."

Again to quote Moynihan: "So far as the symptoms of the hernia are concerned there is little to be said. They may be slight or they may be the sudden symptoms of acute intestinal obstruction which swiftly strike the patient down. In a number of carefully recorded cases, the history of chronic slight digestive or intestinal troubles is usually obtained. The treatment is operative. A number of successful cases have been recorded, namely, by Sonnenberg, Tubby, Priestly Leach, Narth, Habern, Lawford Knaggs, McArthur and Sherren in left duodenal hernia, and Neumann in right duodenal hernia.

"In the majority of cases the mass of the intestines was easily withdrawn from the hernial sac. That this is possible is fortunate, as the neck of the sac cannot be enlarged without dividing the inferior mesenteric vein. This, of course, is out of the question."

Moynihan says that "If the strangulated gut can be drawn out of the sac, the sac should be opened through an incision on the outer side of the vein, the intestines withdrawn, incised in one or more places and emptied of its contents. The incision in the gut must be closed with sutures. It would then be a very easy matter to replace the emptied coils of the intestines and withdraw them through the neck of the hernia. It is desirable to close the neck of the sac by sutures after the hernia is reduced. This is sometimes very difficult."

In reviewing this case it is evident that the correct preoperative diagnosis should have been made, as all the signs of intestinal obstruction were present, together with a distinct globular, tympanitic, tender tumor, lying to the left of the median line, high in the abdomen, as described by Leichtenstern.

As to the treatment, the earlier operation is resorted to the better. The manipulation necessary to reduce a considerable length of incarcerated intestine is necessarilly productive of shock. Multiple punctures of the distended coils I believe would greatly facilitate the procedure. Personally, I feel that in another case I should know where to look for the orifice of the sac, and thus be able to save considerable time. When the mesenteric vessels pass close to the edge of the neck of the sac, as was the case in this instance, its division is, of course, out of the question. The condition is always a very serious one and when strangulated will necessarily carry a high mortality.

Medical Progress.

REPORT ON MENTAL DISEASES.

BY HENRY R. STEDMAN, M.D., BROOKLINE, MASS.

TREPONEMA PALLIDUM IN THE BRAIN IN CASES OF GENERAL PARALYSIS.

THE fact of this recent discovery is already well known, the particulars are as follows:

Noguchi and Moore[1] examined seventy paretic brains, and succeeded in finding the Spirochaeta pallida in twelve cases. The area chosen for examination was usually specimens of brain tissue from the right frontal sphere, but occasionally from the left hemisphere. The twelve positive cases were clinically undoubted cases of general paresis, but of a rapid course. The longest in duration lived only thirty months. The post-mortem appearance, both macroscopical and histological, were the typical lesions constantly associated with general paralysis. No softening, gummata, or marked endarteritis were found. Ten were men, two were women, and five cases were of the tabetic type. The method used for staining was a modified Levaditi silver method, the technique of which the authors do not give. The spirochaetes were found in all layers of the cortex except the outer layer: occasionally they were found subcortically, they were never demonstrated in the vessel sheath, and did not have any particular relationship to the vessels; in the pia no spirochaetes were found. Noguchi and Moore found no ratio between the numbers of spirochaetes and the severity of the paresis, although in one case in which they were most numerous the paretic changes were very marked. They conceive it is possible that the spirochaetes will be found more readily in cases which run a fairly rapid course.

THE SPIROCHAETA PALLIDA IN THE BLOOD OF GENERAL PARALYTICS.

Levaditi[2] has undertaken the investigation of the question whether syphilitic infection in general paralytics is limited to the brain or if it is diffused through the blood and the various organs with accidental localization in the cere-

bral cortex. On November 10, 1913, he read before the Académie des Sciences the results of his researches in collaboration with Dr. Danulesco. The blood of a general paralytic at the third stage, syphilitic fifteen years, was inoculated into the scrotum of a rabbit; at the end of 127 days there was a bilateral scrotal lesion. Ultramicroscopic examination showed many characteristic mobile spirochaetes. The striking feature is the persistence of the parasite in the blood long after the beginning of syphilis—fifteen years. Levaditi and Donulesco had had only one positive result in six trials (five paralytics and one tabetic). It seems, then, that the germ does not exist constantly in the general circulation. Perhaps it appears there only intermittently during the phases which precede or accompany the cerebral manifestations.

GENERAL PARALYSIS WITHOUT REACTION OF THE CEREBRO-SPINAL FLUID.

Demole[3] reports a pronounced case of general paralysis in a man of 44 in which there was a uniform absence of any alteration in the cerebro-spinal fluid. The prodromal symptoms were of six years duration and the probable date of syphilitic infection very much earlier. Apoplectiform attacks, twitching of the facial muscles, unequal and sluggish pupils, exaggerated knee-jerk, extreme affective indifference and intellectual deterioration marked the beginning of his stay in the hospital early in 1913. The disease rapidly progressed, pronounced and characteristic ideas of self-importance, grandeur and wealth predominated and he became absolutely disoriented for time and place. His speech became slow, stammering, slurring and explosive, his handwriting shaky, slovenly and sometimes illegible. The pupillary changes became more marked, his memory defect evident and the fibrillary tremor of the tongue extreme.

Three lumbar punctures were made at intervals of a month with practically the same result in each instance. The cerebro-spinal fluid was invariably clear and crystalline and the tension high. The globulin on the first two punctures was double and on the last less than one-half the normal limit by the Nonne Apelt method and the Szcesi tube—Lymphocytes: 1.9 to 0.5 c.mm. and only faint traces of opalescence on boiling. At each test the Wassermann of the cerebro-spinal fluid was negative and that of the blood was uniformly and strongly positive. During the period covered by the punctures the disease progressed rapidly. Errors of technique are shown to be plainly excluded and the cerebro-spinal fluids of the other general paralytics examined at the same time by the same method and the same solutions gave unmistakably positive results. He regards these paradoxical findings in general paralysis as on a par with examples of the appearance and disappearance of the Wassermann in the course of syphilis, variations formerly considered by some as vital discrepancies the true significance and value of which we only today know how to properly appreciate.

TREATMENT OF GENERAL PARALYSIS BY INTRA-SPINAL INJECTIONS.

Flexner[4] writing on the local specific therapy of infections notes the fact long regarded as notable that notwithstanding the origin of tabes and paresis from syphilitic infection those diseases respond so little favorably to antisyphilitic measures of treatment. Partly for this reason and partly because of the characters of the pathologic changes, they have been separated off from the typical varieties of syphilis and placed in a special category of metasyphilitic or parasyphilitic affections, so called. Now that the *Spirochaeta pallida* has been shown by Noguchi to occur in numbers in the brains of paretics and has never been found in the spinal cord of tabetics, this classification calls for complete revision.

In the meantime how is the disparity in therapeutic response of these affections to be explained? First, there is growing evidence that salvarsan, injected into the blood, may exert a beneficial influence in tabes, but not in paresis. The evidence is derived partly from clinical improvement and partly from the reductions in the cellular and protein contents of the cerebrospinal fluid, and the diminution of the Wassermann reaction. These changes are in accord with the inconstant and fleeting presence of arsenic in the fluid following the intravenous, but not the intramuscular, injection of the drug. Hence it would appear probable that better results might be accomplished provided the drug could be brought with certainty and in suitable concentration into this fluid. Such a method of application, worked out by Swift and Ellis, offers considerable promise of high therapeutic value.

The lesions of the spinal cord in tabes and the clinical symptoms are dominated by pathologic states of the meninges. It is known that in most cases of the disease the cerebrospinal liquid contains the products of irritative or inflammatory conditions existing within the membranes; and microscopic study has revealed areas of chronic meningitis about the radicular portions of the spinal and corresponding portions of cranial nerves. To reach the pathologic processes in the membranes, not in tabes only but in paresis as well, is peculiarly difficult because not only do we have to reckon with the ordinary conditions of impenetrability of the meninges, but there often coexists also an obliterative arteritis of syphilitic origin.

It is not safe to introduce salvarsan directly into the subarachnoid space, and while neosalvarsan, because of its ready solubility, is less injurious, yet the direct injection of that drug is attended with certain risks. Swift and Ellis have taken advantage of the circumstance

that the blood of salvarsan-treated tabetic patients is itself curative, and they have employed the corresponding serum, suitably diluted, for intraspinous injection. The results are both promising and striking. The local irritative condition in the meninges becomes quickly diminished, the Wassermann reaction reduced or abolished and the clinical state of the patient improved. These effects follow even when the salvarsanized blood of other persons is employed for intraspinal injection. They are due, therefore, to the local and not to general treatment.

Nothing less than a careful and thorough trial can determine the applicability of this method to the treatment of paresis. Certain theoretical facts, however, stand well in the foreground. It is known for example, that the cerebrospinal liquid provides a means of direct and immediate contact with the structural tissues of the brain. Whatever chemical is introduced into this liquid will inevitably find its way to the supporting elements, the nerve-cells and fibres of the cortex in which the main lesions of paresis are situated. It is in the cortex likewise that the *Spirochaeta pallida* has now been found, from which it follows that this organism can be best brought under the influence of curative agents through the same channel of communication.

Prediction as to whether or not a direct specific treatment will accomplish the eradication of the spirochaetes in paresis is hazardous for the reason that it remains still to be ascertained whether the spirochaetes which have persisted in the brain are normal or resistant strains. Their persistence for so long a period and resistance to the ordinary healing drugs may, conceivably, be due not alone or wholly to their inaccessibility, but also, more or less, to the acquisition of a state of fastness which, if present, may prove difficult to overcome.

The anatomic conditions existing in paresis are comparable to those occurring in sleeping-sickness and poliomyelitis. In all three diseases numbers of lymphoid cells accumulate within the perivascular lymphatic spaces and degenerations occur in the nerve-cells. Just as the spirochaetes occupy in the cortex in paresis and the trypanosomes in sleeping-sickness, so does the virus of poliomyelitis reside in the tissues of the spinal cord and brain. We have already learned that *Trypanosoma gambiense* can be suppressed by drugs in the blood and lymph-vessels without being destroyed in the central nervous organs, and the virus of poliomyelitis prevented from developing through intraspinous injections of an immune serum that is without effect when introduced to the blood. From this it follows that a local mode of specific treatment offers certain advantages either in theory or in fact not held out in the same degree, at least, by the general method. So far as Flexner is aware local specific treatment has not yet been tested in either paresis or sleeping-sickness. To the former it doubtless will soon be applied; in the latter it should also be tried.

Myerson in addition to his statistical report of the results obtained by him in eight cases by the Swift-Ellis treatment in general paresis embodied in the anniversary report of the Psychopathic Hospital[5] adds the following, which summarizes his remarks in the discussion of this method of treatment at the Boston Medical Library, December 17, 1913. The Swift-Ellis method of intradural injections of salvarsanized serum influences the course of general paresis, as manifested in the changed biological reactions. It does not seem permanently to stay the disease process. Probably this is due to the fact that the lesions of paresis lie outside of the range of the spinal fluid. It is a fundamental fallacy of this treatment in that it supposes the spinal fluid to be an afferent route in relation to the nervous system although it really is an efferent route. If we are to cope successfully with general paresis we must learn to distinguish the pre-paretic stage. The work of William W. Graves, as embodied in the paper: "The Syphilitic Syndrome," (New York Medical Record, August, 1912), and careful serological and spinal fluid examinations in chronic syphilitics presenting any neurasthenic symptoms will help us to distinguish this stage.

Robertson[6] (Geo. M.) raises the question whether we are justified in pushing this antisyphilitic treatment to the extreme. Desperate cases call for desperate remedies, and surgeons operate under conditions in which a definite percentage of their cases are certain to die from the immediate results of the operation, feeling their action justified if the lives of the majority are saved. General paralysis is as desperate a disease as any cancer, for 50 per cent. of those suffering from it die in one year, 75 per cent. in two years and 90 per cent. in three years, and the existence of the few who survive this period is a living death. Are the ethics of the surgeon and physician so different that a principle of the former cannot be followed by the latter under circumstances as hopeless and desperate? Are physicians, then, justified in general paralysis in pushing salvarsan and mercury to the most extreme limits compatible with survival, in the hope of curing at least a percentage of their cases? No doubt under these circumstances, owing to the amount of salvarsan probably required, like the surgeon, the physician would require to be prepared for a certain percentage of deaths from the drug itself. The time seems ripe for a determined effort on these lines, but the weak point in the advocacy of such a course is the fact that, however hopeful the prospects may seem, no one can assert with confidence that a single case would recover. Syphilis, therefore, should be treated when it is possible to cure it, and seeing that the cause of it is known, an accurate test of its activity exists, and a powerful remedy found for it, it will be a slur in the future on the profession of medicine if the seeds of general paralysis and tabes

are permitted to remain in the human soil till it is too late.

CEREBRAL SYPHILIS.

Henderson[7] in a systematic clinical analysis of 26 personally observed cases of cerebral syphilis, in seven of which the diagnosis was confirmed by autopsy finds that cerebral syphilis plays an important part in the production of mental disease, and should occupy a more prominent place among the organic psychoses than it heretofore has done. The spirochaeta pallida has for long been surmised to be the causal organism, but it was not until 1910 that Strasmann first demonstrated its presence in the central nervous system of an adult with acquired syphilis. Trauma, alcoholism, and physical and mental strain are important contributory factors. Re-infection with syphilis is quite possible, provided the initial infection has been thoroughly cured. Anatomically, three main types of cerebral syphilis are differentiated; viz. meningitis, endarteritis, and gumma. Clinically, this differentiation is seldom possible, and is without practical value, as the treatment is the same in all irrespective of the type.

The majority of cases of cerebral syphilis develop within the first three years after primary infection, and rarely more than ten years after infection. This is in striking contrast to cases of general paralysis and locomotor ataxia, which almost invariably develop at a period more than ten years after infection.

In regard to the physical signs, the Argyll-Robertson phenomenon is the one on which most weight should be laid in differential diagnosis, as it is rarely present in cases of cerebral syphilis. Other important features are: (a) an acute onset with headache, dizziness, and vomiting; (b) cranial nerve palsies; (c) convulsions without loss of consciousness, but usually followed by permanent focal symptoms; (d) intactness of speech and writing; (e) absence of facial tremor. Cerebral syphilis not infrequently causes pseudo-bulbar paralysis, and six cases of this affection have been here reported. The mental symptoms of cerebral syphilis are of the nature of those seen in acute organic reactions, and consist of confusion, delirium, amnesia, hallucinations, retention defect, and a poor memory for recent events; in addition there is relatively little disintegration of the personality. The Wassermann reaction must be considered in relation with the clinical picture in each individual case; when the Wassermann reaction with the cerebro-spinal fluid is negative, the diagnosis of cerebral syphilis is indicated. It is frankly admitted that there is no pathognomonic sign for cerebral syphilis; but if the nature and character of the onset and the above-mentioned physical and mental symptoms and signs are correlated, a disease entity is formed which has every right to be considered characteristic. Anomalous features, among which may be mentioned euphoria and grandiose ideas, and confabulatory states, are more common in cerebral syphilis than is generally recognized; special attention must be paid to the setting in which these features occur, because when occurring in a setting of confusion they mean practically nothing. Recent statistics confirm one in the opinion that the prognosis of cerebral syphilis, as compared with other organic affections of the nervous system, is relatively good; the most favorable cases are those of a meningitic or gummatous type. Mercury, no matter in what form administered, is an exceedingly valuable drug in the treatment of syphilis, provided that it is given in a systematic way. The best results are, however, probably obtained by combining mercurial and salvarsan treatment. Potassium iodide acts simply as an eliminative agent, and has no specific action on the spirochaete pallida.

Ravout[8] reports three cases of syphilis of the nervous system in which intraspinous injections were employed. The first case was a woman with secondary syphilis suffering from headaches. She received two drops of a solution containing one-tenth of a milligramme of bichloride of mercury directly injected into the cerebro-spinal canal. The immediate result of this showed itself in a few minutes by an exacerbation of all her previous symptoms, but at the end of three days there was a marked amelioration. Unfortunately this woman was lost sight of, but she served to demonstrate the fact that mercury could be injected directly in the cerebro-spinal canal. The second case was again a female, and she was kept under observation for four years. The chief symptoms were headache, unequal pupils with lack of light reaction, and a partial paralysis for accommodation on the same side. The injection of two minims of a 1+ solution of cyanide of mercruy was given, and the patient had, as a result, a gradually ascending contracture of all the muscles of the body until she was in a state of trismus. This condition lasted fifteen minutes. Four months later, though the headache was much improved, the eye conditions were not good, and a single drop of the former solution was injected. There was again some contractures of the muscles, but only slight. A week later the pupils were equal, but the light reaction was still sluggish. The patient was subsequently treated with salvarsan intravenously. The last case was one of well-advanced cerebral trouble with loss of memory, headache, and an affected gait. Salvarsan was first used intravenously and repeatedly. The symptoms, though at first improved, later recurred, and at the end of ten months the patient's condition was as bad as ever. It was then decided to inject neosalvarsan directly into the cerebro-spinal canal, and this was done and subsequently repeated. The patient's condition improved, but there still remained a certain amount of pain in the feet and a general weakness in walking. The Was-

sermann reaction was changed from a positive to a negative reaction.

ATTEMPTED SUICIDE.

East[9] in an exhaustive inquiry based on a study of 1000 consecutive cases of prisoners charged with attempted suicide concludes that it is an advantage to retain attempted suicide as a misdemeanor. Attempted suicide and suicide are both adversely affected by unemployment and drunkenness, the latter possibly causing more attempts than suicides. Both are similarly affected by the seasons, being more frequent in the hot months. Attempted suicide and suicide differ in the time of day in which they most commonly take place, in the age-incidence, and in the methods most frequently adopted; and whereas attempted suicide is only slightly influenced by the civil status, actual suicide is markedly affected. The family history of attempted suicides shows that in 27.10 per cent. there was parental intemperance, insanity in 10.2 per cent., epilepsy in 0.6 per cent. Of the 1000 cases themselves 2.9 per cent. had been previously insane. Probably all these figures are understated. Physical disease is not by itself a common cause of attempted suicide but at least in France, actual suicide appears to be frequently due to physical suffering. The commonest cause of attempts at suicide are alcoholism, unemployment and destitution, insanity, domestic troubles, morbid mental states not amounting to insanity, and attempts made for an ulterior purpose. Frequently more than one cause exists at the same time. When an alcoholic impulse acts alone in causing an attempt it is more often amnesic, when acting with other causes memory is usually retained. Alcohol incites attempts from impulse, post alcoholic depression, weak-mindedness, and insanity. An attempt during a first intoxication is very rare. In 39.3 per cent. of the cases alcohol was found to be wholly or partially the cause of the attempt. Unemployment is more likely to cause an attempt than destitution. Physical exhaustion is an important contributory cause in these two conditions. Of persons who are charged with committing crime, those whose offence was against the person more frequently attempted suicide than those whose offence was against property. In the weak-minded the attempt may result from very trivial causes, but the reverse not infrequently holds good. Insanity is more likely to cause suicide than attempts at suicide. In the latter 14.1 per cent. were due to this cause, the commonest forms of insanity being states of mental depression and then alcoholic insanities.

PERSONALITY AND OUTCOME IN CASES OF MENTAL DISEASES.

Bond[10] gives four tables showing personalities (or natural mental make-up) and outcome in 200 consecutive cases.

Seventy-four per cent. of these are found described as normal, 26 per cent. as abnormal; 19 per cent. as social, 11 per cent, as seclusive.

Dementia praecox is seen to differ sharply from manic-depressive, alcoholic, post-syphilitic and involution period psychoses in regard to the personalities in which it is found.

Normal personalities are noted in 93 to 85 per cent. of manic-depressive, alcoholic, paretic and involution period psychoses; but in only 29 per cent. of dementia praecox cases.

Seclusive personalities are noted in less than 4 per cent. of manic-depressive, alcoholic, paretic and involutional period psychoses, but in 50 per cent. of dementia praecox cases.

As regards hospital residence only 2½ per cent. of the social cases, in contrast to 50 per cent. of those who showed a seclusive tendency, are still in the hospital at the end of a four-years interval.

GYNECOLOGIC DISEASE IN THE INSANE.

Taussig[11] has examined 537 out of about 900 inmates of the St. Louis City Sanitarium, and found 252 to have some lesion in the pelvic organs sufficient to cause symptoms at present or in the future. These lesions are recorded: 87 suffered from retroversion and 52 from a relaxed pelvic floor. It seems probable that gynecological disease is only slightly more common in insane women than in the sane. In senile dementia, terminal dementia, and paranoia, only about one-third were diseased, in dementia praecox about one-half; among the imbeciles about two-thirds. In the manic depressive group about 74 per cent. showed gynecological lesions, and a large proportion of these showed a chronic inflammatory condition of the genital tract. The number of recoveries from this form of insanity after gynecological operations is so large that when a definite lesion is found it should always be corrected by local or operative measures.

BLOOD-PRESSURE IN THE INSANE.

Sagini[12] who has investigated the blood-pressure of 38 women and 33 men aged from 30 years upwards, suffering from various forms of mental disease, with Riva-Rocci's sphygmomanometer, comes to the following conclusions: There is no constant relation between the number of pulse beats and the degree of blood-pressure. In all mental diseases advanced age determines a rise of blood-pressure. In all mental diseases the curve of blood-pressure in the right arm is a little higher than that in the left. Occasional excitement and emotion of a certain degree is followed by a rapid rise of pressure without a corresponding variation in the pulse. In every form of mental disease food always causes a fall of blood-pressure. The mean blood-pressure of epileptics is lower than that found usually in normal individuals. Their pressure

varies, but never reaches a stage of hypertension, even in the period which precedes or follows the fit. It cannot be affirmed that a definite relation exists between mental conditions and the blood-pressure, nor that constant variations exist in the blood-pressure in relation to every form of mental disease, but there is an obvious tendency to increased pressure in paranoia, alcoholic insanity, and hysteria, and a tendency to low pressure in depressive states.

Reports of Societies.

NEW ENGLAND OTOLOGICAL AND LARYNGOLOGICAL SOCIETY.

A meeting of the New England Otological and Laryngological Society was held at the Massachusetts General Hospital, Tuesday evening, November 18, 1913. The President, DR. GEORGE L. RICHARDS, in the chair.

DR. GEORGE A. WATERMAN, Boston, read a paper on

ELECTRICAL TREATMENT IN TINNITUS.

The normal reaction of an auditory nerve to the galvanic current is best obtained by placing the indifferent pole on the back of the hand, while the testing pole with a small electrode is applied over the mastoid, or just in front of the tragus. When a sufficiently strong current is used with the cathode over the ear, the patient hears a distinct sound with the closing of the current. This sound has varying qualities in different people. It may be a hissing, humming, buzzing or ringing. Sometimes the reaction is elicited with a very modified current; while in some individuals a much stronger current is necessary to produce it. In fact, the current needed may be so strong that symptoms very disagreeable to the patient may result, such as an apparent tipping of surrounding objects, with a sense of giddiness and even faintness. In patients who have a hyperesthesia of the auditory nerve, very little current produces the reaction. Not only the closing of the cathode pole may give rise to the sound, but also the opening of the anode pole may give the same sound, though it is heard less distinctly, while the opening of a cathode and the closing of an anode give no reaction.

In cases where there is a partial degeneration of the auditory nerve, the normal reaction is reversed, that is, the anode pole gives a louder sound than the cathode. This is the so-called reaction of degeneration of the auditory nerve and is analogous to the reaction of degeneration phenomenon seen in disease of the motor nerves, and is, of course, of importance only from the point of view of diagnosis.

I took up the treatment of tinnitus by the use of the galvanic current at the suggestion of Dr. Clarence J. Blake, who described to me his early experience in experimenting with this method, and sent me an article written six or eight years ago, descriptive of good results following the use of the interrupted current applied to the mastoid with the anode pole.

Properly to carry out this treatment, one requires an apparatus that controls the galvanic current with the rheostat, in order that the amount of galvanism given may be graded, and so obviate the unpleasant results which may develop from too sudden an increase in its strength. It is important too, that the apparatus should include a galvanometer in order that the amount of current given may be controlled.

In treating patients I place the indifferent pole on the back of the hand, with a large electrode, and apply the anode pole over the mastoid bone, and then increase the current until the tinnitus ceases. The patient should give his careful attention to the subjective sound in order to determine at just what point it ceases to exist. In some patients a much stronger current is required to stop the tinnitus than in others. In some the cathode may produce this result better than the anode. In many cases neither pole reduces the sound at all. Usually the anode is the effective pole. When the strength necessary to cause the disappearance of the tinnitus is determined, (generally 3 to 6 milliampers,) this strength current is given from three to four minutes, making and breaking the current rhythmically every two seconds, fininshing the treatment by gradually reducing the current to zero by shutting down the rheostat.

As I have said, in many cases the tinnitus is not affected by this treatment. Out of eighty cases in which I have used this method nineteen or twenty have shown improvement in varying degrees. In some the noises have ceased for hours or days; in others the relief has been permanent weeks or months afterwards, as long as the patient was followed; such cases having had from five to ten treatments. In the majority of cases in which improvement was obtained I have written the patient's home physician directions for continuing the treatment. Unfortunately I have not had time to write these patients so I am unable to give absolute statistics as to the permanency of the improvement in all these cases. Dr. Blake and I have intended to compare our notes some time, to see if any definite pathological conditions are especially adapted to the galvanic treatment.

The outlines of a series of cases were given, together with the results produced by the use of galvanism in treatment.

DISCUSSION.

DR. C. J. BLAKE: The original experiments were made forty years ago with an imperfect apparatus. A Stöhrer battery, an ordinary liquid cell battery, the strength of the current being adjusted by means of the slipping of the electrode across a bar, running lengthwise of the battery. It was a very rough adjustment indeed, and one in which it was impossible to get any refinement of application of the remedial current. The experiments made with the Stöhrer battery were, of course, somewhat

hazardous, and having a subjective noise in the left ear, it seemed to me that I was a good subject for test. When this Stöhrer battery arrived, in the latter part of 1870, I proceeded to experiment with it, trying the passage of the current, the anode and cathode, alternating over the mastoids, finding that with an increasing current there was increase in the subjective noise, and with a decreasing current, a decrease in the subjective noise.

Those immediate experiments were terminated by one in which, in consequence of mishandling and sudden interruption of the current, there was a sense of sudden shock by partial unconsciousness lasting for two or three hours, a sense of confusion lasting twenty-four hours, and terminating in a sound sleep. During that period of time, the noise in the left ear was considerably diminished. In further and more guarded experiment with the battery in question upon other subjects, it was found that if the application of the current decreased the circulation sound, it increased the hearing, but the results were not sufficiently satisfactory to make it worth while to continue them beyond a limited period, though they did determine a definite relationship between the galvanic anode, the hearing power and the circulation sound in certain cases. It was a satisfaction to have Dr. Waterman say that he proposed to take up the subject and test the value of this application of the current under a more favorable condition, with a better means of handling it. The first observation, of course, so far as the number of cases in which it was of benefit was concerned, was of very little value, as compared with the observations which he has made, but so far as I remember, the percentage of improvement was just about the same. In two or three cases, with the gross differentiation of current used, there were quite uncomfortable experiences on the part of the patients. In two of the cases, the noises were very considerably increased and the increase in the circulation sound continued in one case for two weeks; in another case for something over a month; in a third, there was not so prolonged an increase of the severity of the circulation sound, but the increase of the circulation sound was accomplished by a general sense of dizziness. There was no distinct vertigo. At any rate, these experiences sufficed to emphasize the statement of the late Dr. Beard that the electric current was a remedy of which it was better to use too little than a little too much.

The treatment which has been followed by Dr. Waterman seems advisable as a test treatment, in cases of severe subjective noises. In 25 per cent., as he has shown, some relief is afforded. Whether that relief is the result of the effect upon the blood vessels and so upon the circulation, the cause of the sound, whether it is the result of the effect induced in the sense centers, or whether it is purely suggestive, is a matter which is still to be determined; and it is to be hoped that Dr. Waterman will continue his investigations.

DR. D. CROSBY GREENE, JR. demonstrated a case of

EPITHELIOMA OF THE VOCAL CORD.

This patient, 41 years old, whom I show you, I operated upon two weeks ago for epithelioma of the right vocal cord, doing the usual operation of thyrotomy. The point of particular interest in this case, which I wish to speak of, is in connection with the after-treatment of the incision. In this case, I put in no sutures at all. I am using no sutures, because in some of my cases where I brought the cartilage together and sewed it tightly, there was a good deal of trouble with emphysema, and also a certain amount of sepsis.

DR. HARRIS P. MOSHER demonstrated a case of

SARCOMA OF THE ETHMOID.

This man, whom I show you, I operated upon a year ago for sarcoma of the ethmoid with involvement of the antrum. Up to the present time, there has been no recurrence and I might say here, it is the only one of this class of cases, that I have operated upon, where there was no recurrence within a year. In operating on this case, I used the Moure incision, and I wish to emphasize this method of operating. By using the Moure incision and method of operating, and by using an electric headlight, I think we are making an advance in the treatment of malignant diseases of the accessory sinuses. Until I tried this method, I was about as skeptical as I think most of my colleagues are, in regard to operating on these cases.*

Dr. Mosher also showed a hook and eye which he had recently removed from the left bronchus of a boy, four years old. The boy had complained of pain in the left side for eleven months. The x-ray showed the position of the foreign body.

DR. C. MORTON SMITH, Boston read a paper on the subject,

HAVE THE EARLY CLAIMS OF SALVARSAN BEEN REALIZED?†

DISCUSSION.

DR. A. C. GETCHELL spoke of two cases in particular where most brilliant results had followed the use of salvarsan. Both were cases of syphilis of the pharynx.

DR. C. R. C. BORDEN related a number of cases of syphilis of the nose and pharynx and of the quick improvement after the use of salvarsan. Dr. Borden was inclined to think that salvarsan should be used preliminary to extensive operations on the nose and accessory sinuses.

DR. S. J. BEACH spoke of two cases. He referred to a case of syphilis of the upper air passages, together with a severe vaso-motor rhinitis; after the use of salvarsan, the symptoms rapidly disappeared. He also called attention to a case of cerebral syphilis associated with severe and sudden deafness. This case cleared up after the use of salvarsan.

DR. F. N. BIGELOW reported two cases of spyhilis of the larynx, in which there was so much infiltration, and dyspnea became so marked that tracheotomy was necessary. The tracheotomy tube was removed after a short time and the cases cleared up under the use of salvarsan.

DR. H. P. ABBOTT reported a case of Vincent's angina, which resisted various treatments until salvarsan was applied locally. Applications were made every few hours and within three days, the throat had entirely cleared.

DR. C. B. FAUNCE mentioned the case of a chauffeur, 24 years old. He saw him a year and a half after the primary infection. He had given four doses of salvarsan at varying intervals. Sudden deafness had come on a month after the first dose had been given. The man is now in the same condition as when he was first seen. There is no improvement in his deafness.

* There has since been a recurrence in this case. Only what is said about this method of operating still holds.

Book Reviews.

A Text-Book of the Practice of Medicine. By James M. Anders, M.D., Ph.D., LL.D. Eleventh edition, thoroughly revised. Octavo of 1335 pages, illustrated. Philadelphia and London: W. B. Saunders Company. 1913.

The eleventh edition of this standard text-book has been carefully revised. An excellent index is one of the most valuable features of a very satisfactory book.

Dreams and Myths. A Study in Race Psychology. By Dr. Karl Abraham, Berlin. Translated by William A. White, M.D., Washington. pp. 74. The Journal of Nervous and Mental Disease Publishing Company. 1913.

This brochure is No. 15 of the Nervous and Mental Disease Monograph Series, and embodies Abraham's studies of classical myths and sagas on the basis of the Freudian psychology, with special reference to the well-known dream theory. It is an attempt to prove that the application of Freud's teaching to primitive fantasies, which have become fixed in the various myths and sagas, may serve as the foundation of a new conception of their origin and development. The same objections which have been brought against the sexual psychoanalytic method in general will, no doubt, be raised against the explanation which the author here sets forth, but this makes its presentation none the less worthy of fair and unprejudiced consideration.

Social Work in Hospitals. A Contribution to Progressive Medicine. By Ida M. Cannon, R.N., head worker, Social Service Department, Massachusetts General Hospital. pp. xi-257. New York: Survey Associates, Inc. 1913. Russell Sage Foundation.

This book, dedicated to Dr. Richard C. Cabot, "whose insight, constructive imagination, and fearless pioneer spirit have been the chief factors in starting and bringing to its present status in this country organized hospital social service," is an admirably temperate statement of the relation of social service to hospital administration and efficiency. Miss Cannon, who has had charge of the development of this work at the Massachusetts General Hospital, is peculiarly fitted to speak with authority on the subject, not only from the viewpoint of a wide experience, but also as a leader in the establishment of an effective social service department in a large general hospital of conservative traditions. As stated in the introduction, the object of the book is to offer interpretations of present-day tendencies rather than to dogmatize as to the significance of work accomplished. In this the author has undoubtedly succeeded, and, if for no other reason, the book should be widely read as a judicial statement of what has already been done, and what may be expected in the future. Following a brief introduction, successive chapters take up the beginnings of hospital social service, the hospital background, the various medico-social problems, the basis of treatment, working together, records, organization, workers, and the future of hospital social service. A useful appendix reproduces various "forms" which have been found useful in the tabulation of cases. We cordially commend the book to physicians, and especially to those who may still entertain doubts of the wisdom of the social service movement, and to all others interested in the broader aspects of medical treatment.

Epidemiologic Studies of Acute Anterior Poliomyelitis. By Wade H. Frost. Washington: Government Printing Office. 1913.

This monograph, published under date of October, 1913, as Bulletin No. 90 of the Hygienic Laboratory of the United States Public Health Service, presents an extensive and careful study of three important recent local epidemics of acute poliomyelitis in this country in three successive years, namely, the epidemic in Iowa in 1910, in Cincinnati, Ohio, in 1911, and in Buffalo and Batavia, N. Y., in 1912. The total number of paralytic cases represented in this combined material was 817, of which 475 were investigated. Investigation was also made of 54 abortive and 71 suspected cases. The work is well illustrated with four maps and 34 charts. The attempt has not been made to correlate the epidemics, except by method of study, but each has been treated as an entity. The data and results both make this work a valuable contribution to the epidemiology of poliomyelitis.

Annual Report of the Bureau of Health for the Philippine Islands. By Victor G. Heiser, M.D. Manila: Bureau of Printing. 1913.

This report records the activities of the Philippine Bureau of Health for the fiscal year ended June 30, 1913. These include the usual functions of a public health service, *plus* those involved by the presence of tropical diseases. In addition to the usual sanitary and hygienic subjects of consideration, there is a careful alphabetic review of these diseases, from albinism to yaws. Foremost among the recommendations of the report is that of "a tax upon polished rice in order to discourage its consumption." This consummation, it is devoutly expected, would greatly reduce infant mortality and would save annually many thousands of lives now lost by beriberi. The second half of the volume consists of statistical tables; reports of divisions, district health officers, and boards of examiners; and a series of sixteen excellent full-page illustrative plates.

THE BOSTON
Medical and Surgical Journal

THURSDAY, FEBRUARY 19, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

MEDICAL LEGISLATION. FEDERAL OR INTERNATIONAL REGULATION OF THE SALE OF BICHLORIDE TABLETS.

THE recent frequency of accidental and suicidal poisoning by tablets containing corrosive sublimate has revived discussion of the need for legislative restriction of the sale and distribution of such tablets. In a recently published interview, Dr. Mark W. Richardson, secretary of the State Board of Health, is reported to have spoken on this subject in part as follows:—

"The intentional swallowing of poison tablets no legislation can prevent. But the public should have all the protection that law can render against the taking of such poisons by accident.

"However, legislation in certain other States would be more important than in Massachusetts, for most of the great drugmaking houses are located in Philadelphia and in Detroit. The ideal solution of the problem is national legislation, affecting all the states, and providing for a protective shape of tablets and packages or bottles containing them, or distinctive colorings, in addition to the labels which most of them bear at the present time. The mercury tablet is of about the same size and has the same feel as various tablets which are harmless, and that makes it dangerous for handling in the dark, when labels count for nothing."

The subject of federal legislation to regulate the sale of bichloride tablets was discussed by Martin I. Wilbert in the weekly report of the United States Public Health Service for Nov. 14, 1913.

After reviewing the statistics of suicides and accidental deaths from scheduled poisons in England and Wales in 1911, the author tabulates a complete series of 27 antiseptic tablets, containing mercuric bichloride, commonly sold in this country.

"Among the many suggestions that have been made to compel uniformity in shape and size of tablets of corrosive mercuric chloride, we have proposals to have them triangular, coffin-shaped, kidney-shaped, and in the shape of a skull, in addition to the various forms already in use."

"Even at the present time there is sufficient legislation, if enforced, to serve as a reasonable safeguard in connection with the sale of corrosive mercuric chloride at retail. No less than thirty-eight States include corrosive sublimate specifically in the laws designed to restrict the sale of poisons, and in but one of the existing laws, that of Utah, are corrosive sublimate tablets exempted from registration in the poison register, otherwise uniformly required for the sale of corrosive sublimate itself. During the present year, three States, Oregon, Nevada, and California, have enacted modified poison laws and specifically enumerate tablets of corrosive sublimate as belonging in 'Schedule A,' drugs, the sale of which is required to be registered in a book provided for that purpose. These several States also specifically enumerate 'antiseptic tablets containing corrosive sublimate,' being so far, the only States recognizing the present-day custom of labeling these very toxic preparations, 'antiseptic tablets.'

"In addition to specific agitation for the proper labeling of all preparations containing poisonous substances, the most promising innovation is the suggestion that a type form of corrosive mercuric chloride tablet or pastille be introduced in the Pharmacopoeia of the United States, with a view of providing adequate safeguards to prevent accidental poisonings. While the suggestions that have been made for this purpose are many and varied, it would appear that, in view of the rapidly growing intercourse between the different countries of the world, it might be desirable to secure international uniformity in regard to preparations of this type. It has been proposed, unless specific and valid objections could be offered, to adopt for inclusion in the Pharmacopoeia of the United States the description of mercuric chloride pastilles included in the German Pharmacopoeia. This latter Pharmacopoeia provides that pastilles of mercuric chloride consist of equal parts of corrosive mercuric chloride and sodium chloride, and requires that the pastilles be colored bright red with aniline dye, have a cylindrical shape, and be twice as long as thick. These tablets or pastilles must be wrapped individually in black paper, bearing the German equivalent of the word poison in white letters. The weight of a tablet must be stated, and the wrapped tablet is to be dispensed only in suitable glass bottles or tubes.

"As an argument for including in the Pharmacopoeia of the United States an official tablet of corrosive mercuric chloride, rather than enacting legislation to compel uniformity in the shape, size, color, and odor of all tablets containing corrosive mercuric chloride, it has been pointed out that inclusion in the Pharmacopoeia would not in any way interfere with the legitimately established trade of manufacturers, but would tend to discourage the sale and use of such preparations."

Whether international agreement would be necessary or practicable in the adoption of a standard bichloride pastille, it would seem that at least some federal legislative action in the matter is eminently desirable. Probably the best solution of the problem, however, would be the replacement of mercuric bichloride as a household antiseptic by some equally efficacious and non-poisonous bactericide.

THE SIGNIFICANCE OF HEADACHE.

There is no symptom which is quite so common in nearly all disordered or diseased conditions as headache. Headache presumably is caused by cerebral irritation of a reflex, toxic or mechanical nature. Usually it is a minor symptom in conjunction with the more important concomitants. Yet this symptom may embrace and be the only outward manifestation of the disease or disorder, and be so varied in its character, distribution, etc., that a study of the symptom, in the few conditions in which it so behaves, will furnish the entire pathological diagnosis.

A headache that is worse on rising in the morning, but which has a tendency to wear off during the day, suggests brain tumor, for the reason that during sleep the intraventricular pressure is lower and can accommodate the increased exudation of fluid which may accompany this condition. On rising, the sudden normal increase of intraventricular pressure impinging against this resisting fluid causes the headache. During the day the increased ventricular pressure prevents the exudation of more fluid, and in fact causes the absorption of some of the fluid already in the ventricle, and thus relieves the headache.

A headache which increases in severity toward evening, and even continues throughout the night points to either a malarial or luetic intoxication,—the severity at this time being due to the nocturnal activity of the parasite and its toxins. Blood examination will easily detect a malarial infection, while a Wassermann reaction test will help to identify a syphilitic infection. In syphilis the headache, besides being toxic in causation, may be due to syphilitic endarteritis of the cerebral vessels, to gummy infiltration of the brain, or to a pure gumma of the brain. In gummy tumor the predominating symptom will be that of a brain tumor, and the toxic character will be masked. If the headache is due to the endarteritis, it would be very likely to be accompanied by apoplectic hemorrhages of greater or lesser severity. In syphilitic infiltration of the brain, the headache might be accompanied by very severe motor, sensory, and even mental manifestations.

A headache coming on regularly in the afternoon or toward evening, and made worse at any time by lying down, and which is usually located in the frontal region, is possibly due to frontal sinus disease In this condition the upright position favors the discharge of the pus through the infundibulum into the nasal cavity.

The so-called reflex headaches are due to irritations of the nerve endings over diseased teeth, in ear disease, refractive errors, etc., in which the irritations from all these places are transmitted to the sensory center in the pons, and thence to the cerebral cortex. It would seem that the cerebral cortex cannot determine whence the irritation came exactly, hence it is that the pain sensation is returned to other places than that from whence it came. For this reason pain areas, the referred pains, are not of much diagnostic help, except that certain irritations are usually referred to definite places, as, for example, tooth irritation to the temporal region, as is also ear irritation.

The condition known as migraine is characterized by the intermittency of the pain, by ocular symptoms, and often by succeeding nausea and vomiting. The pain is often exceedingly severe and the onset sudden. It usually begins on one side and may spread over the entire head very rapidly. The condition subsides just as suddenly as it begins. The causation is undetermined. The present most accepted theory is that it is a reflex neurosis. Others believe it to be toxic in nature, due to the accumulation of uric acid and the xanthin bases. Formerly it was ascribed to a retention of fluid in the ventricles of the brain, caused by a very small foramen of Munro, but this did not explain, any

more than the later theories, its onesidedness. Cyclic vomiting is believed to be the prototype of migraine in infants.

Headache, therefore, may be an unimportant transient irritation, or it may foreshadow a serious pathological condition. Hence the necessity for analyzing each instance, and for ruling out or establishing the presence of a gross pathological condition. Otherwise, when the nature of the headache becomes apparent, it will be too late to apply remedial measures.

ALCOHOLISM.

THE alcohol problem is one of the most difficult civilization has to settle. To this task the Fourteenth International Congress on Alcoholism addressed itself in Milan September last. Italy, although perhaps the largest wine producing country in the world, is said to have had, up to recent years, the smallest death-rate from chronic alcoholism. The historian Ferrero, by the way, in considering the vine in Roman History, declared that wine was an instrument in Romanizing barbarian provinces, the effectiveness of which has been too much disregarded. In Gaul, in Spain, in Helvetia, along the Danube, Rome taught many things,—law, war, road construction, city building, the Latin and Hellenic civilization and arts,—but she also taught wine drinking. Italy has from time immemorial cherished the vine. Oddly enough then, her humanitarians are now realizing the ravages of alcohol among the Italian people and the necessity of a vigorous campaign against this evil. Signor Falcioni in welcoming the delegates on the part of his government, spoke of an impression among some foes of alcohol that the Congress would not be welcomed in a great wine-producing country, and one which derived an immense part of its wealth from that source; but such was a mistaken impression, because his government well understood the object of the anti-alcoholic societies was not the suppression of wine drinking, but a campaign against the abuse of liquor. There were three hundred and fifty delegates, representing many governments and societies, asylums, hygienic institutes and so on.

Signor Falconi declared that up to recent years alcoholism among his people was confined to the cities and the factory workers, but that it is now spreading into the rural districts; and the enormous emigration from the latter has favored the spread of alcoholism, because those going to countries where alcoholism prevails more than in Italy return victims of the habit. And he considers that with the development of alcoholism there has been *pari passu* an increase of tuberculosis, and that there is a close relationship between alcoholism and crime.

MEDICAL NOTES.

TWO LIVING CENTENARIANS.—John Durrant, of Weybridge, England, is said to have been born in 1810. He smokes three ounces of strong tobacco weekly, but drinks no beer and very little wine.

Mrs. Bridget Dougherty Curran, of South Bethlehem, Pa., is said to have been born on Feb. 8, 1807, in Ireland. She still has four aged living sisters.

FIRE IN MILWAUKEE HOSPITAL.—Report from Milwaukee, Wis., states that on Feb. 10 a serious fire broke out in the basement of the municipal tuberculosis sanatorium in the neighboring suburb of Wanwatosa. Forty-five patients were safely removed. The total damage was $50,000.

BERI-BERI IN NEW JERSEY.—In the weekly report of the United States Public Health Service for Feb. 6, 1914, Dr. Herman B. Parker records the results of his investigation of several cases in the county jail at Elizabeth, N. J., which proved to be beri-beri. Twenty-two similar cases during the preceding three years were presumably also beri-beri.

UNITED STATES MORTALITY STATISTICS IN 1913.—Statistics published on Feb. 11, in Washington, D. C., show a general death-rate, for the registration area in 1913 of 13.8 per 1000, the same figure as in 1912.

"Of the eighteen registration states, Maryland, with 16.3 per 1000, showed the highest rate; Minnesota, with 10.7, the lowest. The other states were: California 11.9, Connecticut 14.4, Indiana 12.6, Kentucky 13.4, Massachusetts 14.7, Michigan 13.1, Missouri 12.4, Montana 13.0, New Hampshire 14.1, New Jersey 14.7, New York 15.2, Ohio 13.1, Utah 11.6, Vermont 12.6, Wisconsin 10.9.

"Of the forty-five registration cities, Portland, Ore., with 11.0 per 1000, showed the lowest rate; Memphis, with 22.9, the highest. Other cities' rates were: Birmingham 20.4, Los Angeles 14.0, Oakland, Cal., 12.3, San Francisco 16.7, Denver 14.5, Bridgeport 16.5, New Haven 16.2, Washington 17.05, Atlanta 19.3, Chicago 17.1, Indianapolis 16.3, Louisville 17.2, New Orleans 21.3, Baltimore 19.4, Boston 17.2, Cambridge 13.5, Fall River 18.1, Lowell 16.9, Worcester 16.8, Detroit 19.2, Grand Rapids 13.4, Minneapolis 13.0, St. Paul 13.0, Kansas City 16.3, St. Louis 16.2, Omaha 15.3, Jersey City 16.2, Newark 15.7, Paterson 14.7, Albany 19.2, Buffalo 17.2, New York 16.2, Rochester 15.3, Syracuse 16.3, Cincinnati 17.2, Cleveland 15.7, Columbus 16.2, Dayton 16.3, Toledo 17.0, Providence 15.8, Nashville 19.2, Richmond 22.4, Milwaukee 14.2."

Conference on Medical Education.—The Tenth Annual Conference on Medical Education and Public Health Education and Legislation is to be held in Chicago on Monday and Tuesday of next week, Feb. 23 and 24, under the auspices of the Council on Health and Public Instruction and the Council on Medical Education of the American Medical Association. Among the papers to be presented is one by President Lowell of Harvard on "The Danger to the Maintenance of High Standards from Excessive Formalism."

An Indian Centenarian.—White Eagle, a chief of the Ponca tribe, who died on Feb. 5 at Ponca City, Oklahoma, is said to have been born in 1803, and was supposed to be the oldest Indian in the United States.

Cancer Mortality in Königsberg.—Statistics recently published show that in 1880 the cancer mortality in Königsberg, Germany, was 53 per 100,000 of population. In 1893 it was 110; in 1907 it reached a maximum of 139. Since then it has steadily declined and in 1912 was 118. This recent decrease is believed due to the popular educative propagandum, initiated in 1907, which has led to earlier diagnosis and greater readiness to accept prompt and radical surgical treatment.

A Transfer of Authority.—Report from Washington, D. C., on Feb. 8 states that the bureau of food and drug inspection of the United States Department of Agriculture has been abolished. Its functions and authority will hereafter be exercised by the bureau of chemistry.

BOSTON AND NEW ENGLAND.

A Living Centenarian.—Morris D. Shimelovitch, of Brockton, Mass., who is said to have been born on Feb. 8, 1811, in Russia, celebrated recently his supposed one hundred and third anniversary. His health is excellent, and he walks outdoors daily.

Fire in Lawrence Hospital.—A fire occurred on Feb. 9 at the Lawrence (Mass.) General Hospital, but was extinguished before serious damage was done. Several patients were removed from their rooms, but no one was injured.

NEW YORK.

Health Federation.—The Health Federation of the City of New York, an association composed of some 150 organizations interested in matters of public health, was organized at a meeting held at the New York Academy of Medicine on Feb. 4, at which Dr. J. H. Huddleston presided. The plan of organization includes the establishment of an advisory body, to be known as the Central Council of Public Health, consisting of fifteen members, and among those appointed on the council were Dr. Huddleston, Dr. C. L. Dana, chairman of the Public Health Hospital and Budget Committee of the Academy of Medicine, Dr. Philip Van Ingen, medical advisor of the New York Milk Committee, and B. B. Burritt, acting general director of the New York Association for Improving the Condition of the Poor. At the meeting Dr. L. K. Frankel, one of the vice-presidents of the Metropolitan Life Insurance Company, reported that during the past year his company had sent visiting nurses to the homes of 17,000 of its industrial policy holders, making 108,000 visits at an expense of $61,000; E. S. Elwood, secretary of the Committee on Mental Hygiene of the State Charities' Association, described the work of the committee; and reports were made by representatives of various other organizations.

Division of Rural Hygiene.—The members of the State Grange, gathered in convention at Poughkeepsie on Feb. 5, were startled to learn from the health committee of the organization that while during the past year the death-rate in New York City was 13.7, in the country districts, villages and towns of less than 8,000 population of the state it was 15.4, and a recom-

mendation by the committee, urging the establishment of a special division of rural hygiene in the State Department of Health, was endorsed.

PAVILION FOR VENEREAL DISEASE.—An annex to the Long Island College Hospital in Brooklyn has been opened which is solely devoted to venereal diseases. The new pavilion, which has accommodations for 60 male patients, is two stories in height, the upper floor being reserved for gonorrheal cases and the lower floor for syphilitic. This is a welcome addition to the city's hospital facilities, for, with the exception of possibly one or two, none of the private hospitals have heretofore accepted patients suffering from venereal diseases, and those needing hospital treatment have been obliged to enter the public hospitals. For patients who are willing to pay for the privilege of greater privacy, two small wards, one on each floor and with four beds each, have been provided. The most approved modern treatment is assured by the hospital authorities, and specially trained male nurses are in attendance.

MORTALITY STATISTICS.—The weekly reports of the Health Department show that the mortality in the city in the month of January represented an annual death-rate of 14.80, as against 13.33 in December and 14.46 in January, 1913. The weekly average of deaths from measles increased from 9 in December to 12.5 in January; the weekly average from scarlet fever, from 5.25 to 11.25; from whooping-cough, from 2.5 to 3; from diphtheria and croup, from 22.75 to 31; from influenza, from 7.25 to 13.5; from epidemic cerebrospinal meningitis, from 2.75 to 3.25; from pulmonary tuberculosis, from 157.5 to 191; from pneumonia, from 107 to 133; from bronchopneumonia, from 85 to 108.25; from cancer, from 85 to 91; from apoplexy and softening of the brain, from 23.25 to 29.75; from organic heart diseases, from 208 to 241; from appendicitis and typhlitis, from 9.75 to 12.75; from cirrhosis of the liver, from 15 to 16.5; from Bright's disease and acute nephritis, from 113.25 to 123.5; and from puerperal diseases, from 9.25 to 15.25. Among the few diseases in which there was a decrease in mortality were the following: The weekly average of deaths from acute bronchitis declined from 15.25 to 13.76; from tuberculous cerebrospinal meningitis, from 11 to 9.5; from diarrheal diseases under five years, from 31.75 to 29.75; and from hernia and intestinal obstruction, from 15.25 to 12.75.

HOME SEGREGATION OF TUBERCULATES.—In last week's issue of the JOURNAL we commented briefly on the report recently published by the New York Association for Improving the Condition of the Poor, on its work in the home isolation and treatment of families made dependent by tuberculosis. In a model tenement, 27 such families, including 79 tuberculates, were segregated, and given fresh air, food, work and medical care.

"Eleven of these families, containing 23 tuberculous patients, 12 of whom were wage-earners, were discharged during the year. Six of the eleven families were rehabilitated, physically, socially, and economically. The other five had to be dismissed for persistent intemperance or refusal to follow advice. The condition of these, however, as a consequence of the treatment received was improved.

"No new cases of tuberculosis developed after admission. Sixty-one per cent. of the adult patients apparently were cured, 23% had their diseases arrested and 11% were much improved.

"In only four cases was there no progress. The improvement of the 65 children and 16 infants also was satisfactory. Eighteen of these were consumptive, 23 were suspicious cases, and most of the others were excellent candidates for the disease. At the end of six months, each child had reached a weight normal for its age.

"Upon admission to the hospital the average income of the six families was $6.42. When discharged the average weekly income of these families was a trifle less than $15."

This method, which may be regarded as an adaptation and extension of the "tuberculosis class" employed in Boston, is expected to produce social and economic rehabilitation as well as physical regeneration.

1. Lovett advises the use of hexamethylenamin in suspected cases of infantile paralysis, absolute rest in the acute stages, with abstinence from massage and electricity till all tenderness is over and prevention of contractures by passive means. As soon as tenderness is over, generally at the end of four weeks, massage, electricity and muscle training are begun, of which the latter is the most valuable. Operative treatment and braces come later. This is a short, concise and very excellent article on this subject.

3. Willson emphasizes the importance of abundant fresh air, as near a milk diet as possible, forced water, frequent thorough cleansing of the gastro-intestinal tract, even with castor oil, every second or third day and avoidance of over-medication, as the important points in the successful treatment of pneumonia.

10. De Tarnowsky advocates the seemingly very radical procedure of pouring sulphuric ether into the abdominal or pelvic cavities at operation for pelvic or general peritonitis. In 30 cases no deaths have resulted. [E. H. R.]

THE JOURNAL OF EXPERIMENTAL MEDICINE.

JANUARY 1, 1914.

1. *WIGGERS, C. J. *Does Cardiac Rhythm Alone Determine Human Blood-Pressure Variations?*
2. KRUMWIEDE, C., JR., AND PRATT, J. S. *Observations on the Growth of Bacteria on Media Containing Various Anilin Dyes.*
3. GILLESPIE, L. J. *The Acid Agglutination of Pneumococci.*
4. *HANES, F. M. *An Immunological Study of Pneumococcus Mucosus.*

8. TTOMAS, W. S. *Experimental Hydrocephalus.*

1. Wiggers concludes that changes in cardiac rhythm are not the only determinants of blood-pressure variation in man. Heart-rate changes seem to be the only determining influence in blood-pressure variations in the minority of cases. The majority of cases show the intervention of respiratory influence.

4. Hanes studied the organisms described by Schatmüller under the name of Streptococcus Mucosus, which were obtained from six cases of lobar pneumonia. Inasmuch as his study showed that this well defined group of organisms had definite characteristics which indicated a closer relationship to the pneumococci than the streptococci, he prefers the name of Pneumococcus Mucosus.

5. Rous and Murphy have continued their studies of the production of tumors by means of an emulsion of fresh tumor that passes through a Berkefeld filter. They studied three entirely different varieties of chicken tumors. The filtrate in each instance when injected into another animal, only give rise to growths of the precise kind from which it has been derived. They believe that a group of entities, which are, of course, cell-free, exist in the filtrates, which cause in chickens neoplasms of diverse character.

6. By a comparative study of a trout hatchery in different years, Marine concludes that goitre in fish is a symptomatic manifestation of a fault of nutrition. In this particular hatchery water played no essential part in the causation of goitre. The determining factor seemed to be the diet. [R. I. L.]

12. SHEA, A. W. *The Operative Treatment of Fracture of the Olecranon.*

1. Magruder cites a case of comminuted fracture of both bones of both legs, in which the x-ray showed strikingly similar pictures. One leg was treated by the closed method; the other by an open method with plating, with the result that consolidation occurred four weeks earlier on the closed side. From this and similar experiences, he advocates the closed method in the treatment of fractures when an approximately anatomical coaptation can be secured, but considers operation indicated when there is wide displacement of fragments, and in particular fractures when ankylosis threatens. When operation is indicated, it should be performed as early as possible in order to wash out blood clots and tissue shreds, to bring the soft structures into closest approximation to the bone for the elimination of dead spaces and for splint effect, and in order to relieve the system of the unnecessary task of absorption. To maintain fixation in cases where there is tension, heavy plates are to be avoided, on account of the size of the foreign bodies introduced, which tend to cause pressure necrosis and infection. He finds tinned-steeled-annealed wire, passed partially through the cortex between periosteum and medullary cavity, without entering the canal at all, the best method when applicable, and especially in oblique and spiral fractures. For this procedure he used a grooved bone drill, through which wire is easily passed after the hole is made, and before the drill is withdrawn.

5. Albee points out that in cases of pseudo-arthrosis in ununited fractures in the ends of the fragments there is sclerosis or eburnation, due to a diminution or entire cessation of osteogenetic activity of the cells, with an over-deposit of calcium salts. The therapeutic requirements to meet this condition are fixation, stimulation of osteogenesis in the fragments, and an osteogenetic scaffold connecting the active bone in each fragment back of the eburnated areas. The Lane plate furnishes fixation only; the bone transplant fulfills the last two requirements, and if inlaid furnishes fixation as well. He cites illustrations in a series of fifteen cases of pseudo-arthrosis, in all of which bony union was obtained. His method consists in inserting a notched tibial graft into a groove in the fractured bone. Accuracy of approximation of graft to groove is obtained by the use of a twin saw with parallel blades, the graft being held in place by kangaroo tendon passed through drill holes in each fragment. In cases of ununited hip fracture, he dowels out a bone peg from a tibial graft, and drives this into a hole motor-drilled in the great trochanter through the center of the neck into the capital fragment.

9. Cotton calls attention to all different forms of injury to the astragalus that are likely to be met with. Some of these, when overlooked, give extraordinarily poor functional results; whereas, if the condition is recognized, the reduced cases recover extraordinarily well. The varieties mentioned are too numerous to be reviewed in this column, but the article will afford a valuable chapter to anyone interested in the diagnosis and treatment of injuries to the ankle.

[G. A. L., JR.]

THE LANCET.

10. DAVIES, D. L. *Modern Treatment of Lachrymal Obstruction.*

1. In the first part of this article Wright and others discuss the causation, prophylaxis and treatment of the pneumonia which affects native laborers, and in particular the tropical native laborers in the Rand mines. He discusses the preparation of vaccines, technic and dosage, scheme of administration and maximum dosage, and describes in detail various complex experiments on this subject. So far the results show that the natives' natural deficiency in pneumo-opsonic power does stand in some causal relation with his low resisting power to pneumococcic infections.

[J. B. H.]

JANUARY 10, 1914.

1. *WRIGHT, A. E., MORGAN, W. P., COLEBROOK, L., AND DODGSON, R. W. *Observations on Prophylactic Inoculation Against Pneumococcus Infections and on the Results Which Have Been Achieved by It.*
2. *FRASER, H., AND STANTON, G. T. *Unpolished Rice and the Prevention of Beri-beri.*

7. SKEVINGTON, J. O. *Secondary Hemorrhage from Deep Epigastric Artery after Operations for Appendix Abscess.*
8. KENNEDY, A. M. *Rupture of the Heart by External Violence.*
9. CATON, R. *Health Temples in Ancient Greece and the Work Carried on in Them.*

1. In this second paper, Wright and others describe their results obtained from therapeutic and prophylactic inoculations of pneumococcus vaccines. The results of treatment of the disease itself showed

nothing in favor of the inoculation method. As a prophylactic method, there was a slight percentage favoring those who were inoculated against the uninoculated cases. They do not recommend any general inoculation against pneumonia, but they urge the further pursuit of investigations in this direction.

2. Fraser and Stanton discuss rice, polished and unpolished, and its relation to beri-beri in the Malay peninsula. They urge that effort be made to prepare a palatable form of unpolished rice and that its use be made obligatory by law if necessary. [J. B. H.]

British Medical Journal.

1. *Gould, A. P. *An Address on Radium and Cancer.*
2. *Morison, R. *A Clinical Lecture on the Triple Syndrome in Abdominal Emergencies.*
3. *Osler, W. *An Address on the Medical Clinic: A Retrospect and a Forecast.*
4. Mackenzie, J. *On the Teaching of Clinical Medicine.*
5. Sprawson, C. A. *A Family with Cerebellar Ataxia.*

1. Gould states that "the true therapeutic use of radium rests upon its selective affinity for cancer cells and not upon a general caustic or destructive power." He then cites in detail five cases and discusses the dangers of this treatment such as danger to the operator, sloughing, thrombosis, hemorrhage and constitutional reactions. He then takes up the limitations of this treatment as regards inaccessibility, metastases, painful local reactions, etc. and whether or not radium should be used as an alternative to operation, citing four cases in which radium seems to be acting favorably in place of a most extensive operation. The article is of great interest.

2. This is a clinical lecture on abdominal emergencies based on eight illustrative cases.

3. This article of Osler's is sufficiently described by the title. It is of great interest and should be read by every one connected with medical schools and medical teaching. [J. B. H.]

January 10, 1914.

1. *Barr, J. *Pneumonia: Its Nature and Treatment.*
2. *Browning, C. H. *Investigations on Syphilis as Affecting the Health of the Community.*
3. MacLaurin, C. *The Treatment of Hydatid of the Liver.*

5. Mayberry, G. M. *The Administration of Guiacol in Pulmonary Tuberculosis.*
6. Rudolf, R. D. *Epidemic Cervical Adenitis.*

1. This is an excellent clinical article on pneumonia. Barr here considers the incidence of the disease, its relation to race, sex, age; he takes up etiology, prevention, causes of death in adults and children. He discusses the causes of cardiac failure, the use of the abdominal ice bag, the maintenance of systolic blood-pressure, ventilation, etc. In the general principles of treatment he emphasizes the need of sleep; he advocates the use of lime salts, such as calcium chloride, etc., making claims for this method of therapy which, to say the least, must be difficult to substantiate. On the whole, the article is full of common sense except as regarding drugs. If each patient were given all those he recommends, his stomach would become a veritable apothecary shop, and the results might not be good.

2. Browning, in an interesting article, considers syphilis and its relation to public health. His investigation was based on the clinical examination of the patient, the examination of the members of his family, the history of the patient and his family, and the result of the Wassermann test with the blood of the patient and of the members of his family. In this study he takes up the prevalence of congenital syphilis, mental deficiency and epilepsy, heart disease in children, deafness in children, ozena, aortic disease, nervous diseases, eye disease, metritis etc. and its relation to syphilis. His conclusions urge further use of the Wassermann reaction, more thorough treatment in hospitals and institutions whenever possible. [J. B. H.]

13. Bucky, and Silberg, M. *A Compression Tube with Bucky's Effect.*
14. Abahary. *Charles Richet.*

1. Ehrlich and Karrer have made a preparation of salvarsan and copper, assuming that the antiseptic action of these two metals together might be greater than that of either one alone. Baermann has used the new drug, therapeutically, in 45 cases of amebic dysentery, frambesia, malaria and leprosy. He describes the method of administration of this compound, the dosage, and the clinical studies which he has made with its use.

The drug had no effect in amebic dysentery, but gave striking results in the local and general treatment of frambesia, in tertian, quartan, and pernicious malaria, and in leprosy. Baermann considers these observations of a preliminary nature, but concludes that the results show for the drug a high chemotherapeutic strength.

9. Gibson has collected six cases of splenic tumor, of which three clinically were Banti's disease, among 300 autopsies or operations. Two distinct types of lesion were observed. In the first, the spleen was infarcted and contained small areas of pigmentation. In the second microscopic examination was more normal except for an excessive amount of blood and for increased trabeculations. The interesting feature of these cases, however, was that sections from each case stained by Wheal and Chown's method showed the presence of streptothrix filaments differing morphologically in the different types of lesion. Although cultures from the organs were negative, Gibson assumes that the splenic lesions were due to the streptothrix infection and that an agent of this kind may be the cause of certain cases of Banti's disease. [R. F.]

4. *BOSS. *The Relation between the Gall Bladder and the Chemical Reactions of the Stomach.*
5. JACOBS. *Granular Contraction of the Kidneys in Childhood.*

4. The gall-bladder has been considered of importance in preventing a constant flow of bile into the duodenum, irrespective of need for it, and in preparing a thicker and more efficient bile for the digestive processes. Various investigations have been made to determine the effect on gastric secretion of the loss of gall-bladder function, whether through its removal, or obstruction in the cystic duct. Hohlweg has stated that in this condition there usually results either hyperacidity or anacidity. The author presents brief examinations of twenty cases, which do not bear this out at all,—many show entirely opposite results. He agrees with Magnus that, so far as can be determined from the cases examined to date, a continuous, unchecked flow of bile, or on the other hand a diminished one, do not cause regularly either hypo- or hyperacidity. He considers that no definite conclusions can be drawn as to the effect of cholecystectomy on the secretion of hydrochloric acid.

[R. H. M.]

WIENER KLINISCHE WOCHENSCHRIFT.

No. 50. DECEMBER 11, 1913.

7. STRISOWER, R. *My Experiences in the Cholera Epidemic in Servia During the Summer of* 1913.

2. The author cites 38 cases of dysmenorrhea treated with atropin, of which 30 reacted favorably. The method of the action of atropin is not definitely known, but supposedly it reduces the force of the uterine contraction or lowers the patient's sensitiveness to them. In the former instance it might be of value in preventing imminent miscarriage. [F. S. K.]

1. PHILIPOWICZ, J. *Appendicitis in Old Age.*
2. *HOFBAUER, T. *The Clinical Significance of Thorax Depression.*

2. The author draws the following conclusions: It has generally been supposed that narrow thorax predisposes to phthisis. Czerny by investigation has proved that it occurs more frequently in children with full rounded chests and in whom the respiratory excursion is comparatively small. In such children the thorax is in a constant state of expansion, and though the static alveolar air is increased the renewal of air is diminished. From the above the author believes that in the usual methods of respiratory exercise that the value of inspiration is exaggerated and that deep expiration is at least fully as important. [F. S. K.]

4. FIESCHI, D. *New Tissue.*
5. *HAMANT, AND PIGACHE, R. *Critical Study of Coccygodynia.*

1. Crile's article is a restatement of his familiar theory of anoci-association.

2. Billet believes that anterior approach to the elbow-joint is indicated for capsulorraphy, arthrotomy, or localized bone lesions.

3. Leveuf presents an embryologic study in explanation of the occurrence of pericolic veils and ligaments.

5. The authors believe that the term coccygodynia should be reserved for pain exclusively located in the coccyx. It is due to luxation of the coccyx from external or internal violence. The only treatment is surgical, complete resection of the coccyx, which cures the coccygodynia without involving functional disabilities. [R. M. G.]

REVUE DE MÉDECINE.

JANUARY, 1914.

1. *DEBRÉ, R., AND PARAF, J. *Complement Fixation. The Reaction of the Antigen.*
2. HAMBERT, G., AND ALEXIEFF, W. *Contribution to the Study of Cancerous Meningitis.* (*Conclusion.*)

1. In a long series of cases Debré and Paraf have performed complement fixation reactions upon the urine of patients suspected of genito-urinary tuberculosis. The antigen was, at first, a source of considerable difficulty, since all the substances employed showed great variation in sensitizing power. The latter, when once established, remained in most instances in its original strength only for a short time

The anti-serum of man, small laboratory animals and artificially protected horses and cows, was employed. Great variation was found from serum to serum and between different samples from the same animal. The serum of the horse was at last found the strongest and most lasting, and was used in the bulk of the work cited in this paper.

The urine from the suspected patient or from the suspected kidney is employed in varied dilutions, and the latter with the antigen and complement is mixed with the hemolytic system. The procedure from this point is similar to that used in the test of Wassermann. When the tests and controls react in the expected manner no trouble results. But, the antigen may become, through age or accidental infection, antihemolytic. The latter can be avoided by proper care in preserving the serum.

On the other hand, the urine, in certain instances, shows such an anti-hemolytic power. This difficulty is overcome with cloudy urines by centrifugalization of the specimen, diluted 1:10. When the urine is clear its anti-hemolytic power is titrated and a sufficient amount of complement is added to neutralize or attach the free antibodies in the urine.

In all, 128 tests were performed upon 83 patients. The findings have been confirmed by animal inoculation and in many instances by pathological examination of tissues removed at operation.

The results show an extremely high percentage of positive readings in cases which were known to be tubercular or were subsequently proved so. The converse is also true.

The importance of this simple and immediate test for the determination of unilateral tubercular renal involvement can scarcely be overestimated.

[L. H. S.]

Miscellany.

MASSACHUSETTS MEDICAL SOCIETY.

STATED MEETING OF COUNCIL.

A stated meeting of the council of the Massachusetts Medical Society was held at the Boston Medical Library, Feb. 4, 1914, at twelve o'clock noon, the president being in the chair and eighty-eight councillors present.

The minutes of the last meeting were read and accepted.

The following delegates were nominated by the chair and duly appointed:

Delegates to the American Medical Association for two years: J. B. Blake, Boston; alternate, Gilman Osgood, Rockland. H. G. Stetson, Greenfield; alternate, L. A. Jones, North Adams. L. F. Woodward, Worcester; alternate, J. F. Burnham, Lawrence. For one year, alternate, R. I. Lee.

Delegates to Maine Medical Association: F. W. Snow, Newburyport; F. W. Anthony, Haverhill.

Delegates to New Hampshire Medical Society: J. B. Thomes, Pittsfield; C. S. Adams, Wollaston.

Delegates to Rhode Island Medical Society: J. H. Gifford, Fall River; E. W. Burt, Westport.

To Connecticut State Medical Society: F. B. Sweet, Springfield; Philip Kilroy, Springfield.

To National Legislative Committee of the American Medical Association, Feb. 23, at Chicago, C. F. Withington.

To Conference on Medical Education, Feb. 24, and to the Association of American Medical Colleges, Feb. 25, at Chicago, H. C. Ernst.

The secretary read the petition of one Fellow for reinstatement, and a committee was appointed to consider the petition.

The reports of the committees appointed to consider the petitions for reinstatement of six Fellows were acted on by the council separately. Five were reinstated and one rejected.

The secretary read two letters from the American Medical Association inviting him to attend a meeting of the secretaries of the state medical societies at the building of the American Medical Association in Chicago on Feb. 25, and to present to this meeting the plan of organization of the Massachusetts Medical Society.

Dr. Arnold moved, and it was

Voted, That the council authorize the secretary of the Massachusetts Medical Society, or some member to be chosen by the president, to attend the proposed meeting of secretaries of the state societies and the conferences to be held at Chicago, Feb. 23 to 25, and that the society defray expenses other than those paid by the American Medical Association.

A letter was read from Wisner R. Townsend, secretary of the Medical Society of the State of New York, advocating the payment of the expenses of the delegates to the House of Delegates of the American Medical Association by the trustees of the American Medical Association. This was discussed by Dr. Arnold, who said: "Having served as delegate to the American Medical Association for several years, and knowing that matters of this sort are considered by the trustees in a very fair spirit, and that they are ready to do everything that is for the good of the association and of the state societies that comes within their means, and inasmuch as this has been presented to the trustees, and it is a question of ways and means, about which we know very little, it seems to me that we are hardly in position to take action at the present time. If the trustees should vote in favor of such action and the association pays the expenses, we should be very glad to be relieved of that expense. If the trustees decide at the meeting that it is inadvisable, I understand that the New York State Society is to bring it before the House of Delegates, and I move that this matter be referred to our delegates at the next meeting of the House of Delegates of the American Medical Association for their consideration at that time."

It was so voted.

The treasurer read his report for the eight and one-half months ending Dec. 31, 1913, and the report of the Auditing Committee was read by Dr. J. L. Huntington.

Voted, To accept the reports.

The report of the Committee on Membership and Finance was presented by Dr. F. W. Goss, recommending that two members be transferred from one district to another, that six be placed on the retired list, and that fourteen be allowed to resign.

Voted, To Accept the report and adopt its recommendations.

The Council voted the following appropriations for the standing committees:—

Of Arrangements	$3000
On Publications and Scientific Papers	$3000
On Ethics and Discipline	$100
On State and National Legislation	$300
On Public Health	$25

Also that three thousand dollars ($3000) from the treasury be distributed among the district societies.

On a query by a councillor as to how the dividend is distributed, Dr. Buckingham said that by a vote passed some twenty or thirty or forty years ago, the dividend is distributed among the different district societies in proportion to the amount of the dues collected by the district treasurer previous to a definite date, the object being to spur district treasurers to get in payments promptly. The time when payments should be considered in advance or in arrears was in the past at the close of the annual meeting. Last year when the new by-laws were made, a provision was inserted that this time should be brought forward, so that now it is the first of June. Thus, in order that a district may be entitled to draw anything on this rebate, payment of dues must be made before June 1.

The dividend is not distributed according to the number of members in a district society, but according to the amount of dues paid up. The society which sends in twenty-five dues with seventy-five members gets just one-third as much as the society which sends in the whole seventy-five dues before the stated time.

Dr. G. B. Shattuck presented the report of the Committee on Publications and Scientific Papers. He read the propositions submitted by Dr. Homer Gage at the meeting of the council on Oct. 1, 1913, and the vote referring the matter to the Committee on Publications, requiring a report at the next meeting of the council. (See BOSTON MEDICAL AND SURGICAL JOURNAL, Oct. 9, 1913.) The report of the committee was as follows:

"The Committee on Publications and Scientific Papers have considered the proposition that the Massachusetts Medical Society should take over the BOSTON MEDICAL AND SURGICAL JOURNAL, and do not consider this step would be wise, even if the owners should consider favorably such a scheme.

"The committee have considered the proposition that the Massachusetts Medical Society should issue a monthly bulletin of its own, and believe that the association with the BOSTON MEDICAL AND SURGICAL JOURNAL, outlined below, offers greater advantages both to the society and to the JOURNAL, and they therefore do not favor the independent issuance by the society of a monthly bulletin.

"The committee have considered the proposition concerning the change in the method of issuing the various publications of the society and a possible closer association with the BOSTON MEDICAL AND SURGICAL JOURNAL, and after conferences with the owners of the JOURNAL, offer the following suggestions, which have already been favorably considered by the owners.

"1. That some connection between the Massachusetts Society and the BOSTON MEDICAL AND SURGICAL JOURNAL is advisable and feasible.

"2. That the BOSTON MEDICAL AND SURGICAL JOURNAL be incorporated under the laws of Massachusetts.

"3. That after incorporation, the owners agree to give one share of stock to each member of a committee of three, to be appointed by the Massachusetts Medical Society, one of whom shall be the secretary of the society, which committee shall serve with the owners as directors of the BOSTON MEDICAL AND SURGICAL JOURNAL, having control over its affairs.

"4. That when a representative of the Massachusetts Medical Society shall cease to serve on this committee he shall surrender his share of stock to the owners.

"5. That the owners agree that as long as the association with the Massachusetts Medical Society shall continue they will transfer their stock only to physicians approved by the board of directors.

"6. That there shall be added to the editorial staff of the JOURNAL, to be appointed by the directors and with the approval of the editor-in-chief, an editor, or editors, who shall represent the Massachusetts Medical Society, and be members of the regular editorial staff of the JOURNAL, having a voice in the conduct of the JOURNAL, as well as in matters which peculiarly concern the society.

"7. That in consideration of the advantages expected to be realized by the Massachusetts Medical Society from its association with the BOSTON MEDICAL AND SURGICAL JOURNAL, and in further consideration of the fact that in the opinion of the present publisher such association may at least temporarily entail increased expense to the JOURNAL, to meet which there are at present no available resources, the Massachusetts Medical Society agrees, if it is necessary in the opinion of the directors, to furnish to the directors from its funds a sum not to exceed two thousand dollars a year for three years, to compensate the JOURNAL for possible financial loss arising from its association with the Massachusetts Medical Society.

"8. That if the association between the Massachusetts Medical Society and the BOSTON MEDICAL AND SURGICAL JOURNAL be terminated before three years have elapsed, the Massachusetts

Medical Society shall not be held financially responsible for any losses to the JOURNAL after the end of the calendar year in which the association is terminated.

"The Committee on Publications and Scientific Papers further recommend:—

"1. That if the above suggestions are adopted, the society abandon the separate publication of its proceedings and medical communications, and that as far as practicable it publish these and all other matter only in the BOSTON MEDICAL AND SURGICAL JOURNAL, in such form as may be later determined. These publications shall be sent to each member of the society.

"2. That as soon as possible some arrangement be made whereby each number of the BOSTON MEDICAL AND SURGICAL JOURNAL be furnished to each member of the society.

"3. That a special committee of three, one of whom shall be the secretary of the Massachusetts Medical Society, as previously stated, be appointed, with power to carry out the recommendations of the council and to serve with the owners as directors of the BOSTON MEDICAL AND SURGICAL JOURNAL for one year."

After some discussion, participated in by Drs. H. Gage, Worcester, Cotton, J. B. Blake, Crowell, Bartol, and Arnold, it was voted to accept the report.

On motion by Dr. J. B. Blake, the privileges of the floor were given to the members of the Committee on Publications and Scientific Papers, and Drs. Taylor and Osgood explained the provisions of the report. They favored a committee of three to consider and put into effect the recommendations of the committee.

Dr. Gage favored a committee to which to refer the report for further consideration on account of the importance of the matter. Dr. Crowell suggested that the question be referred to the Committee on Membership and Finance. Dr. Gage said it was immaterial to him whether it was given to a small committee, the Committee on Membership and Finance, or to an even larger committee, but on general principles, he believed that a smaller committee would be more efficient. Dr. Cotton thought the committee should be a larger one and representative of the state at large, and he moved that the committee consist of the following four officers of the society: president, vice-president, secretary, and treasurer, and five members of the council to be nominated from the floor. Dr. Harrington thought it would be better to have the five appointed by the chair, and proposed this as an amendment to Dr. Cotton's motion. The amendment being accepted by Dr. Cotton, the motion as amended was put by the president and was carried unanimously.

On motion by Drs. Palmer and Cook, it was voted to have the report of the Committee on Publications and Scientific Papers printed and sent to the members of the council, together with a report of the proposed committee of nine.

Dr. Ryder read the following report of the committee appointed to consider the working of the malpractice act:

"Your committee appointed to consider what if any changes should be made in the 'Act for the Defence of Suits for Malpractice,' report that they recommend that the articles stand for the present as they are, with such explanations as are herein described.

"Interpretations of the articles as given by the committee seemed to clear the atmosphere of misunderstanding and to give the secretary of the society a more succinct translation of them.

"Our conclusions were based largely on a report which Dr. George W. Gay received from the secretaries of the various state societies which have a Medical Defence Act, in response to a number of questions which he propounded.

"The epitomized summary of those replies is as follows:—

"The following state medical societies, twenty in all, have a medical defence act for the protection of their members when sued for malpractice: New York, New Jersey, Pennsylvania, Illionis, Iowa, Michigan, Massachusetts, Minnesota, California, Kentucky, Kansas, Indiana, Maryland, West Virginia, North Dakota, Nebraska, Mississippi, Missouri, Vermont, and Wisconsin. In replies to inquiries from all except the last, the following facts show a remarkable unanimity of opinion and practice in the framing of the acts and in the enforcement of the same.

"The act has been in force in the various states from two to twelve years, New York being first in the field, and having had a very large and a very successful experience in its use. The act is satisfactory in all the states with possibly one exception, the only state in which any move has been made to repeal the law.

"The average number of suits brought annually in the different states varies from none to about twenty-five or thirty. Of course a much larger number of threatened actions call for consideration by the medical defence committees, and are disposed of in various ways without coming to trial. In fact, this is one of the chief values of the act.

"The approximate annual expense of the act in the different states varies from nothing to six thousand dollars. Only one spends more than thirty-five hundred dollars annually. During the five years that the Massachusetts Medical Society has had the act in force the annual expense has averaged $385, or about eleven cents annually for each member.

"None of the state societies pay verdicts. They pay for counsel and court fees and perhaps a few other contingent expenses.

"Most of the societies do not pay the medical experts anything except travelling expenses, etc. Only four pay any expert fees and those are only nominal.

"Most of the societies defend their members in all civil suits regardless of the merits of the case. The decision of this question rests with the medical defence committee in all the societies. Two states have no separate committee, the work being done by the president and secretary.

"Private insurance is not generally encouraged. A few advise protection in damages, but not in defence alone. The objections to insurance against verdicts lie in the supposition that it encourages suits for the purposes of obtaining hush money, or settlements without trials. This can be obviated by a restraining clause in the policy.

"Many of the societies aid those carrying private insurance, some dividing the expense with the company. Others only advise, but do not incur any expense. Nearly all of the societies recommend their members to depend upon their counsel; in other words, to place their cases immediately in the hands of the societies for defence. It must be apparent to all that the earlier a case receives investigation the better for the defence.

"The evidence in relation to the advantages of the Medical Defence Act is overwhelmingly in its favor. In only one state has any effort ever been made to repeal, and that was not successful. The medical associations through appropriate committees can do this work much better than any agency. They understand the nature of the situations far better than any others can. They are not in the work for the money they can get, but only to protect the innocent from imposition and fraud. As a rule the societies do not settle cases, and under no circumstances do they pay damages. Hence there is no inducement for a threatened suit with that in view. They may advise the defendant in certain cases to settle, but he pays the bills, not the society.

"The suggestions for amendments to the act as read at a previous meeting of the councillors, which had for their ultimate aim a better understanding of the several articles of the act were as follows:

"1. 'The consideration of excluding from the benefits of our Defence Act all Fellows who have insurance with commercial companies.'

"The committee report that any Fellow according to *Article first* of the act, may avail himself of the privileges of this act, but that it is not the intent of the act to join hands with commercial insurance agencies. It is urged that all Fellows when possible place their defence in the society's keeping.

"2. 'A more exact definition of the sort of suits to be defended by the society: Should a member palpably negligent or culpable be defended—or only those Fellows whose suits involve blackmail?'

"Most of the state societies do defend their members in *all* civil suits regardless of the case, the actual decision resting with the Medical Defence Committee. Your committee recommend that in our society the decision of this question in any individual case be left to the judgment and discretion of the president and secretary as specified in *Article fourth*.

"3. 'Are any suits to be settled? If so, when is the society to assent to the settlement by the Fellow? Should the society ever pay anything toward a settlement?'

"It is recommended that the president and secretary be empowered to *advise* settlement whenever in their judgment such course seems discreet and wise, but that the society shall not assume any responsibility for payment of such settlement.

"4. 'Should medical experts called by an attorney in suits against our Fellows receive any remuneration from the society?'

"It is recommended that expenses only be paid by the society.

"5. 'Should a regular committee be appointed to consider the various questions arising with reference to malpractice suits, *i.e.* a committee on medical defence?'

"While most of the states do have such separate committees, it is recommended in our case that the president and secretary constitute such an advisory board as provided in *Article fourth* of the act.

"6. 'Is further advertising of the act advisable?'

"Your committee say no! Ignorance of the existence of the act is fast being abolished. Every member on joining the society is furnished with a copy of this act.

"7. 'Should all members irrespective of their means, be urged to avail themselves of the benefits of the act, or only those in straightened circumstances? Should Fellows be encouraged to give up commercial insurance and rely on our act?'

"It is recommended that all members avail themselves of our defence whenever possible, to the end that suits brought for the purpose of obtaining hush money may be deterred. Private insurance that pays damages engenders suits. Society defence discourages suits.

It is further recommended that the committee on medical education make some inquiry relating to the amount of instruction on ethics given in the various schools, whose diplomas we recognize, particularly with reference to malpractice suits and the fact that the majority of such suits have been brought as a direct result of the attitude of a fellow practitioner."

Voted, To accept the report and adopt its recommendations.

The committee appointed to draft resolutions on the death of Dr. R. H. Fitz, consisting of F. C. Shattuck, J. Collins Warren, George W. Gay, L. M. Palmer and Alfred Worcester, reported through Dr. Gay, as follows:—

Resolved, That in the death of Dr. Reginald Heber Fitz the Massachusetts Medical Society,

the medical profession, and the community suffer a grievous loss. Born in 1843, taking his M.D. from Harvard in 1868, he then passed two years in Europe, grounding himself thoroughly in the pathology of that day under Rokitansky in Vienna and Virchow in Berlin. His quality was promptly recognized and he was appointed instructor in pathological anatomy in the Harvard Medical School in 1870, succeeding Dr. J. B. S. Jackson as full professor in 1878. In 1892 he was transferred to the chair of theory and practice, resigning in 1908, when the age limit, then in force, retired him from the visiting staff of the Massachusetts General Hospital, to which he was appointed in 1887. He thus rounded out thirty-eight years as a teacher of medicine. Notable as were his services as a teacher of students and wise promoter of advance in teaching methods, his greatest services were as a teacher of the profession. In 1886, he read before the Association of American Physicians his masterly paper on "Perforating Inflammation of the Vermiform Appendix," which forced almost instant conviction that the appendix is the most frequent source of the dreaded "inflammation of the bowels," and also clearly setting forth the salient diagnostic features and surgical treatment. He also proposed the term "appendicitis," which has been universally adopted. In 1889, came his Middleton Goldsmith lecture on "Pancreatitis," again shedding a flood of light upon ill-understood conditions. The paper on pancreatitis showed in an equally high degree with that on the appendix the application to clinical medicine and surgery of accurate pathological knowledge, painstaking collection and sifting of the literature of the subject, and logical reasoning therefrom.

It is safe to say that no physician in recent times did more than Fitz to transfer treatment from the physician to the surgeon. And yet he was always conservative as regards operation and saw clearly the dangers inherent in the *furor secandi* sired by the safety of clean surgery. In his anniversary discourse before the New York Academy of Medicine in 1901 on "Some Surgical Tendencies from a Medical Point of View," and again in his presidential address to the Congress of American Physicians and Surgeons in 1907, entitled "The Border Land of Medicine and Surgery," he applied the curb to the excess of operative zeal. The character of his work and the rapid diffusion of knowledge secured merited recognition while he was still in his prime, and he was fortunate in enjoying for years the appreciation of his notable services to mankind.

Chief among the many honors which came to him were the presidency of the Congress of American Physicians and Surgeons and the Honorary LL.D. from Harvard. He was always ready to serve the Massachusetts Medical Society in any capacity, and was orator in 1894, choosing as his subject, "The Legislative Control of Medical Practice," and treating it with his characteristic thoroughness and lucidity.

He was a firm and loyal friend, with a warmth of heart best known to those who knew him best.

The society and the profession of medicine have lost a shining light; humanity has lost a friend. Let us take his example to heart, and strive, each according to his capacity and opportunity, to emulate, though we cannot hope to rival it.

Voted, To accept the resolutions and send a copy to the family of Dr. Fitz.

The secretary read a communication from the New England Sub-Committee on Obstetrics of the American Association for the Study and Prevention of Infant Mortality, as follows:

The New England Sub-Committee on Obstetrics of the American Association for the Study and Prevention of Infant Mortality called a meeting on December 20, 1913, at the Boston Medical Library to talk over informally the midwife situation in Massachusetts and whether or not it was advisable to act in favor or against any possible legislation which may be introduced into the Legislature of 1914 in the State of Massachusetts. There were asked to this meeting representatives of the medical societies, philanthropic societies interested in the care of pregnant women, social workers, certain physicians, especially from the mill cities in the eastern part of the state. There were about thirty people present at the meeting, Dr. H. W. M. Bennett of Manchester, New Hampshire, told of the workings of the Manchester City Mission where a group of public-spirited physicians with the help of certain philanthropic individuals in the city have done practically all the obstetrics among the poor in the city of Manchester, which is largely a mill town. Dr. Arthur B. Emmons spoke of the work of the Maverick Dispensary at East Boston, where there were no students but the work is carried on by two physicians who give their services for five dollars for each case. Many questions were asked of the workings of the City Mission in Manchester and the Maverick Dispensary in East Boston, and it was made clear that it was not necessary to have students in the community in order that the poor of the community may obtain good obstetric service. After a free discussion, Dr. Emmons brought before the meeting a set of resolutions which, after discussion and some changes, were adopted as follows:

Whereas, one hundred and fifty or more women are illegally practising as midwives, and

Whereas, a proportion of the immigrant population are utilizing these midwives to obtain obstetric services as shown by various investigations, and

Whereas, this problem has been met successfully in at least one industrial city of New England having a large immigrant population, and

Whereas, private organizations in Boston are meeting the necessity among a portion of its immigrant population, and

Whereas, the required standard of obstetrical proficiency for admission to practice of medicine in the State of Massachusetts is admittedly low, and

Whereas, a movement is on foot aimed to put the midwife in the immediate future on an equal standing with the physician before the law, Therefore

Be it resolved that this meeting, held under the auspices of the New England Sub-Committee on Obstetrics of the American Association for the Study and Prevention of Infant Mortality, urge the Massachusetts medical societies, through their geographic units, to organize immediately to meet the above situation in their respective districts by providing obstetric service especially to the large immigrant class, and

Be it resolved that the State of Massachusetts through the Board of Registration in Medicine be urged to amend its laws so as to bring them into conformity with modern medicine.

Be it further resolved that a copy of these resolutions be sent to the Board of Registration and the Massachusetts medical societies.

This was discussed by Dr. Cook, and it was

Voted, To accept the report.

The president nominated Dr. J. W. Stimson as councillor and supervising censor for the Worcester North District Society, to fill a vacancy, and he was appointed.

The resignation of Dr. F. W. Goss as a member of the Committee on Membership and Finance was read by the secretary. Dr. Gay said that this communication separates an old officer from the committee, and moved that in commemoration of his long and faithful service a rising vote of thanks be extended to Dr. Goss for his service.

The motion was put and all rose.

The president nominated Dr. Alfred Worcester to fill the vacancy made by Dr. Goss' resignation, and he was appointed.

Adjourned at 1.45 p. m.

WALTER L. BURRAGE, *Secretary.*

SOCIETY NOTICES.

NEW ENGLAND PEDIATRIC SOCIETY.—The thirtieth meeting of the New England Pediatric Society will be held in the Boston Medical Library, Friday, February 27, 1914, at 8.15 P. M.

The following papers will be read:

1. "Bacillus of Contagious Abortion," Dr. Marshall Fabyan.
2. "Inclusion Bodies in Scarlet Fever," Dr. Lewis B. Hill.
3. "Under what Conditions is the Diagnosis of 'Tuberculosis' in Children Justified?" Dr. John B. Hawes, 2d.
4. "A Voice Sign in Chorea," Dr. Walter B. Swift.

Light refreshments will be served after the meeting.

DR. CHARLES A. PRATT, *Pres.*
DR. FRITZ B. TALBOT, *Sec'y.*

BOSTON SOCIETY OF MEDICAL SCIENCES.—The next meeting will be held on Tuesday evening, Feb. 24, 1914, at the Nutrition Laboratory of the Carnegie Institution of Washington, Vila Street, Boston, Mass., at 8.15 o'clock. The meeting will be conducted by the staff of the Laboratory.

Papers will be presented as follows:—

Mr. T. M. Carpenter, "Effect of Dead Space in Respiration Apparatus." (15 minutes.)

Dr. Francis G. Benedict, "Demonstration of Respiration Apparatus in Rabbits." (10 minutes.)

Dr. Raymond Dodge, "Quantitative Technic for the Knee-jerk." (15 minutes.)

Mr. H. L. Higgins, "The Effect of Posture on the Alveolar Air." (15 minutes.)

Dr. H. M. Smith, "The Measurement of Pulse-Rate by the Oscillograph." (10 minutes.)

Dr. Francis G. Benedict, "A Thirty Day Fast." (15 minutes.)

THOMAS ORDWAY, *Secretary and Treasurer,*
Harvard Medical School.

THE NORFOLK DISTRICT MEDICAL SOCIETY.—A regular meeting of the Society will be held at Masonic Temple, 171 Warren Street, Roxbury, Tuesday, Feb. 24, at 8 P.M. sharp.

Business. Communication: "Personal Identification," illustrated. Gustaf Gustafson, Secret Service Bureau.

Refreshments after the meeting.

BRADFORD KENT, M.D., *Secretary.*
798 Blue Hill Ave., Dorchester.

MASSACHUSETTS GENERAL HOSPITAL.—A surgical meeting, open to the medical profession, will be held at 8.15 p. m., on Friday, Feb. 20, 1914, in the lower amphitheatre of the out-patient department. Entrance on either Blossom or Fruit Streets.

The following papers will be presented:—

"Cancer of the Uterus," by Dr. Farrar Cobb.

"A Study of Bloood-Pressure in Hysterectomies and Other Radical Operations," by Dr. Harold Giddings.

APPOINTMENTS.

DR. WILLIAM C. BRAISTED, medical inspector U.S.N., has been promoted and confirmed surgeon-general and chief of the bureau of medicine and surgery of the Navy Department.

RECENT DEATHS.

DR. CHARLES E. SMITH of Whitesboro, Oneida County, N. Y., a graduate of the Albany Medical College in 1858, died from cerebral apoplexy on Jan. 28. For twenty-three years he had been postmaster at Whitesboro.

DR. CHARLES E. FROELICH, who died on Feb. 1 at Hartford, Conn., was born in 1843. He received the degree of M.D. in 1870 from the University of Copenhagen, Denmark. He had practised his profession in Hartford since 1873.

DR. A. F. LE DOUBLE, who died recently at Tours, France, was born in 1845. He was professor of anatomy at the Tours Medical School, and was noted especially for his work on the variations of the muscular system and of the bones of the skull, face and spine.

DR. EDWARD PAYSON FOWLER, who died of pneumonia on Jan. 29 at Pelham Manor, N. Y., was born in Coshocton, N. Y., on Nov. 30, 1834. He received the degree of M.D. in 1855 from the New York Medical College and practised his profession in New York City for over 50 years. He was a member of the New York Academy of Medicine, the New York Neurological Society, and the Medical Society of the County of New York. He is survived by his widow, by two daughters, and by one son.

DR. G. LLOYD MAGRUDER, who died of heart disease recently at Washington, D. C., was born in 1848. He was at one time dean of Georgetown University Medical School. He is survived by his widow, by one daughter, and one son.

DR. DANIEL C. LOGUE, who died on Feb. 3 in Bellmore, L. I., was born at Otisville, Orange County, N. Y. in 1832. After graduating from Wesleyan University, he obtained the degree of M.D. from the New York Medical College. At the outbreak of the Civil War he entered the naval medical service. He became surgeon of the *Monitor*, and is believed to have been the last survivor of her famous engagement with the *Merrimac*. After the close of the war, he settled at Brooklyn, N. Y., where he continued active in the practise of his profession until his retirement in 1900. He is survived by two sons, both also physicians.

A STUDY OF SOME TYPES OF DISTURBANCE OF THE STOMACH AND INTESTINES ASSOCIATED WITH ADHESIONS INVOLVING THE INTESTINAL TRACT, AND THEIR TREATMENT.

By Henry F. Hewes, M.D., Boston.

The influence or function of adhesions involving portions of the gastro-intestinal tract, as a cause of pathological conditions or disturbance of health and function in the body, has always been something of a problem in medicine.

That adhesions, the result as a rule of some inflammatory affection in the abdominal cavity, as appendicitis, or ulcer, or cholecystitis, or tuberculosis, or the result of surgical operation upon the abdominal organs, do cause such disturbance of the bodily welfare with the production of symptoms, has long been a well recognized fact. The extent to which this pathological factor acts as a cause of disturbance, has, however, only recently become well understood, when through the perfection of the method of investigation of the stomach and intestines by the x-ray under the administration of bismuth, it has become possible to diagnose the existence of adhesions and the resulting mechanical effect of these upon the anatomy and physiology of the gastro-intestinal organs, without actually inspecting the abdominal cavity by operation or post-mortem examination.

As a result of the study of this subject under these conditions we have gained much light in regard to the manner of action of this pathological factor as a cause of bodily disturbance, and of the symptomatologies and clinical pictures which are associated with it. This manner of action of adhesions involving the stomach or intestines is very varied.

The primary action of adhesions appears to be either actual constriction or fixation, binding down to the peritoneum or to other organs, of a portion of the gut. As a result of such action we may have anatomically an actual narrowing of the lumen of the gut at the point of contact, or a kinking or looping, at this point or above it or below it. Even actual strangulation of gut or marked interference with blood supply may occur. Or we may have as a result of such constriction or fixation, a drawing of a portion of the stomach or intestines out of normal position, with the production of an abnormal bending or kinking, or simply a functional disability of the gut, in some portion far removed from the actual location of the adhesions.

With such distortion of the gut we get physiologically a disturbance of normal peristalsis and of the passage of the contents of the gut, in the portion affected, the portion where the constriction or kinking, or drawing out of position, whether at the point of adhesion or removed from it, occurs. Such a condition may give rise to the retardation or stasis of stomach or intestinal contents, above or even below the region where the physiological action of the gut is abnormal, or simply to accumulation of gas in portions above the region, or in other cases to increased rapidity of movements of contents by and below the point affected. Associated with the condition such symptoms as pain and distress, distention, constipation diarrhea, flatulence, vomiting, and marked nerve disturbance, or disturbance of nutrition, or possibly symptoms of so-called auto-intoxication may occur.

This constricting or fixing, or drawing out of position of portions of gut, in addition to the actual mechanical distortion of gut which is affected, appears also, in some cases, either as a result of some mechanical action, or by the abnormal functional conditions which are produced, as stasis of contents in the intestine, etc., to give rise to disturbances in the integrity or function of the gastro-intestinal tract, through the agency of reflex action. Thus in cases, spasm, or abnormality of peristalsis of portions of gut, stasis of contents or gas, may occur in portions far removed from the actual seat of lesion without the finding of any anatomical variation in the portion where the function is disturbed. For example, disturbance of the stomach, with imperfect emptying of contents, may occur in cases where no distortion of the stomach or duodenum is present, and where the only abnormality found is adhesions about the cecum and ileo-stasis of contents.

With the great diversity in the location of adhesions involving the gut, and in the forms of distortion which they cause, and with the complicated manner of action of these abnormal conditions upon function, it is clear, *a priori*, that the symptomatologies found in association with this condition of adhesions causing disturbance in the body, must be very varied. As a matter of fact they are, running well through most of the types of symptomatologies of gastro-intestinal disturbance, and of various types of nerve disturbance as well.

Many cases of this kind have, for example, the one symptom of constipation with perhaps some associated abdominal discomfort. Others with or without constipation complain chiefly of flatulence, accumulation of gas, distention, of all-gone sensation and depression.

On the other hand, some cases have violent pain and colic, and tenderness, suggesting appendicitis, or duodenal ulcer, others have severe diarrhea, others gastric symptoms of distress in the epigastrium, belching of gas, vomiting.

The symptomatologies depend to some extent doubtless upon the location of the actual lesion, or the point where the actual distortion of the gut, or functional disturbance induced by the lesion, occur. Exclusively gastric symptoms,

for example, occur more frequently where the adhesions are located near the stomach or high up in the intestine. However, they may occur where the actual adhesions are at the cecum, the fixation at the point and the dragging out of position of the gut resulting, causing distortion at the pylorus or in the position of the stomach. Or they may occur here apparently simply as a reflex from conditions lower down.

Lesions involving the same portion of intestine may in two cases give very different sets of symptoms. Thus some cases with fixation or constriction of the cecum, may have constipation, others may have alternating constipation and diarrhea, others continuous diarrhea, all depending partly upon the actual functional disability which the lesions set up, as retarded peristalsis with stasis in one, extra peristalsis or spasm of the ileo-cecal valve in another, and partly doubtless upon the nervous temperament and constitutional character of the individual affected.

A majority of these various symptomatologies found in association with adhesions, or distortion or disturbance of the gastro-intestinal tract due to adhesions, are clearly in no sense pathognemonic of this condition, since similar symptomatologies are found in association with other pathological or functional disturbances of the body. For example, constipation with some sign of abdominal discomfort, perhaps the most common symptomatology of adhesions, is a frequent finding of purely functional disturbance of the intestines, or of various conditions of organic disturbance other than adhesions. The continuous diarrhea often seen with adhesions is a symptom of functional disturbance, inflammatory colitis, improper assimilation of food. Alternating constipation and diarrhea is a common symptom of mucous colitis and of nerve disturbances. The stomach symptoms seen with adhesions are often similar to those found in nervous dyspepsia, in some cases of ulcer of the stomach and duodenum, and in gall stones.

Diagnosis or probable diagnosis that the symptoms in any given case are the result of adhesions can be made only by supplementing the study of symptoms with an x-ray examination, and in case of a positive finding, an exclusion of definite evidence of other conditions capable of causing similar symptomatologies.

Treatment of conditions of disturbance due to adhesions depends in each case upon the exact character of the pathological lesion or functional disturbance caused by the adhesion. In many cases complete relief of symptoms may be secured by a proper system of medical, as distinguished from surgical, treatment. In other cases surgical interference alone can produce a cure.

Since adhesions and their results are a common cause of conditions of disturbance, and since we possess successful methods of treatment of many of the conditions having adhesions as the primary cause of disturbance, and since the treatment is special in these cases, depending upon an understanding of the exact conditions present, it is essential, that in all cases of gastro-intestinal disturbance which cannot be accounted for by the accurate diagnosis of the existence of other pathological conditions, the possibility of adhesions as the cause of symptoms should be considered, and investigated by proper methods.

As an illustration of this subject, the influence of adhesions as a cause of conditions of disturbance of the stomach or intestines, and of the character and efficacy of special forms of treatment for the relief of these disturbances, I give the records of some cases, selected from the many cases of this type of malady which have come under my observation.

CASE 1. Male. Age 35. For at least 25 years the patient has been subject to frequent attacks of diarrhoea. The spells of looseness last from several days to two or three weeks. The number of movements vary. As a rule there are three or four a day—always very loose. Movements are of brown color. Mucus or blood have never been noticed by the patient. There is pain or cramp at times before a movement. At other times during the attack there may be a dull disturbed feeling in the abdomen. Attacks are more frequent in summer but occur throughout the year.

Food stuffs with large unutilized residue, as fruits and green vegetables always promote diarrhoea—but the trouble may occur on any diet. At times the patient has gone a month without an attack. He may have spells of one regular daily movement, without drugs, for a period of weeks between attacks. Then comes a period of constipation and then an attack. At other times he is constipated throughout the interval.

For the last three years the amount of diarrhoea, and of intestinal discomfort when not having diarrhoea, has been much increased. In 1911 the patient was operated upon for the removal of his appendix. Evidence of the previous inflammation of the appendix was found. Since the operation there has been just as much trouble as before.

There have never been any symptoms of dyspepsia, such as distress in upper abdomen after food, eructations of gas, etc.

The patient loses and gains weight by times but thinks he is always under weight.

Physical Examination: Condition of nutrition good. Haemoglobin 100. Heart and lungs normal.

Examination of faeces, obtained during a spell of looseness, shows a loose unformed stool, not watery, of brown color. No mucus or pus present. Blood test negative. Food elements all increased in amount over normal but no excess of any one form, when patient was on a test diet, as the Schmidt diet. The faeces were excessively acid.

X-ray examination with Bismuth shows

1. No abnormality as to stomach or duodenum.
2. Fixation of caecum to abdominal wall.
3. Marked 9 hour ileo-stasis, some 24 hour stasis in lower ileum, caecum, and ascending colon.
4. The transverse colon in its first portion shows a marked downward loop.

The x-ray report reads: "marked ileo-stasis with fixation of caecum by adhesions and an abnormality

of the transverse colon suggesting the possibility of kinking at this place."

The record of the case with the clinical history of alternate constipation and diarrhoea, the finding of ileo-stasis, of adhesions fixing the caecum and of the abnormality in the colon, suggests the following theory of the case.

As a result of a tendency to stasis of contents in the intestine, due probably to the fixation of the caecum and the abnormality in the anatomy of the colon, the intestines are not freely emptied regularly. The backed up intestinal contents, either by fermentation and consequent irritation of the gut, or by reflex action coming as a result of the abnormal quantity present, induces, at periods, increased peristalsis to relieve the condition, and periods of diarrhoea follow.

Acting upon this theory of the case the patient was placed under the regular administration of agar agar powder, mixed with small portions of calcium carbonate, with the idea of keeping the bowels regular without the use of cathartic drugs, that is to prevent the gradual backing up of the intestinal contents which in the past has preceded the diarrhoea attacks.

The diet used consisted of meat, fish, eggs, bread, potato, macaroni, rice, simple cereals, peas, custard, ice cream, eliminating foods with large refuse as fruits or green vegetables.

This system was installed June last. Since that time the bowels have moved daily with good full formed movements. There has been but one period of looseness, occurring about two weeks after the system was started, and this lasted but two days.

Otherwise there has been a complete disappearance of symptoms. This period of five months of freedom from symptoms is much the longest that the patient has ever had, and the result of the study of the case has so far indicated that the malady, or abnormal condition, can be controlled by this method of treatment.

CASE 11. Male. Age 55. In 1886 the patient had a bad attack of diarrhoea in the summer lasting two weeks. Since that time he has been subject to occasional periods of diarrhoea lasting for a few days. These periods he has found as a rule follow a few days of constipation. For most of the time however between 1886 and 1910 his bowels have been regular and he has suffered only from the occasional attacks of constipation and diarrhoea coming perhaps three or four times a year.

In 1910 he was operated upon for the removal of the appendix. The organ was found to be acutely inflamed with some serum in the peritoneal cavity. Since this operation he has suffered almost constantly from constipation and has had to use drugs regularly for his bowels. There has been the same history of an occasional spell of looseness independent of the use of cathartics. In this period he has suffered at times from dull distress in his lower abdomen.

In 1911 in July he had a severe attack of diarrhoea lasting three weeks which was called colitis by his physician. He had several short attacks of diarrhoea up to October. From October, 1911 to July, 1912 he was constipated with rare short periods of diarrhoea. Since July, 1912 he has had alternate periods of constipation and diarrhoea, and marked intestinal discomfort much of the time. That is he has been constipated for a period of 2—3 weeks then had a few days of diarrhoea, then another period of constipation.

In the diarrhoea periods the faeces have contained much mucus. No blood noted.

Sept. 1st in London he had an x-ray investigation. The report of this examination is as follows.

"Marked ileo-stasis and caecal-stasis. Evidence of an abnormal condition of the walls of the caecum. Evidence of the existence of adhesions in the region of the caecum."

In London where his symptom at the time was constipation with much intestinal discomfort, he was placed on a treatment of paraffin oil and senna, used daily, and he has been on this treatment since. Under this regime he has had continual looseness of the bowels, one to three daily movements, and much discomfort.

He has not noticed that diet has much effect upon his trouble in the past.

Examination Nov. 8, 1912.

Physical Examination Normal. Haemoglobin 100. Examination of faeces—stool very loose and filled with gas bubbles, mucus present, no pus. The faeces were very acid. Blood test negative.

In the early history of this case we find a tendency to an occasional period of constipation followed by a day or two of diarrhoea. For most of the time the bowels were normal.

After the appendix operation constipation became a continual trouble with an occasional loose spell. It seems probable that this condition of constipation was due principally to the effect of the adhesions about the caecum following the appendicitis, or the operation for the removal of the appendix.

In recent periods with the more marked constipation, the diarrhoea spells have been much more severe and the amount of intestinal discomfort much increased.

During the last months there has been continued looseness, due probably to the constant use of cathartics, and continued intestinal discomfort.

As a result of the study of this case the theory was adopted, as in the first case, that the spells of diarrhoea were due primarily to the constipation, and tendency for the contents to collect or stagnate in the intestines. The primary cause of the trouble was in this case adhesions and injury to the intestinal wall.

The first step in the treatment of this case was the removal of all cathartics, under the use of which the patient had not prospered, to study the case under natural conditions. Injections of oil were given to promote defecation.

Under this regime the patient would go for several days with regular movements, then there would come a day of much intestinal discomfort followed by explosive diarrhoea. The faeces passed on these occasions were very foul. No one predominant form of bacteria could be isolated. Always a large growth of colon bacillus was present. An excessive growth of the gas bacillus was present.

Apparently even with the enemata there was the same tendency to stagnation of contents high up, which characterized the case, less marked with the enemata but still present, and the following intermittent periods of diarrhoea.

The patient was then placed upon regular administrations of agar agar powder and calcium carbonate.

Under this regime large daily defecations of formed faeces occurred, the occurrence of diarrhoea spells became less frequent and finally ceased. The

patient is now going upon doses of agar alone, and is practically without symptoms for months at a time.

These two cases, with evidence of the existence of adhesions and abnormality of the gut in the region of the cecum and first portion of the colon, show a marked similarity in their clinical character. In both we have as the principal symptom the intermittent occurrence of periods of constipation and diarrhea. In both the symptoms yielded to the same form of treatment devised to prevent the occurrence of the stagnation of the intestinal contents by promoting regular peristalsis all along the line.

The clinical findings in the two cases differed, however in one important feature. In number one the examination of the feces never revealed any abnormality save the looseness of the stools, with the evidence of excessive fermentation. In number two, however, mucus was always found present in the earlier examinations of the feces. In other words, the second case had some resemblance to the condition known as mucus colitis, in which as you know, the symptoms are frequently of a type similar to those seen in this case, that is, symptoms of alternating constipation and diarrhea. This observation on this case is one of many which tend to substantiate the well- known theory that many conditions described as mucus colitis are in reality symptom-complexes representing the result of the existence of adhesions involving the colon.

This type of symptomatology seen in these two cases represents one of the most common clinical pictures associated with adhesions involving the intestinal canal. In cases with this type of symptoms the lesion is as a rule in the region of the caecum or colon, or possibly the ileum. The cases come to the physician complaining, as a rule, of the diarrhea. But it is the constipation which must be treated, even in the cases which do not show the ordinary sign of constipation, that is, cases which have a regular daily movement of the bowels.

Before instituting treatment in these cases the physician must first establish the fact that adhesions, or distortion of the intestine, or caecal- or ileo-stasis are present. For the symptomatology alone does not necessarily mean this condition. It may occur from other causes where the specific treatment used here is not efficacious, as, for example, in some cases of actual colitis, in conditions of neurosis or debility, or from improper diet. Once assured that the lesion in question is present as a probable cause of the symptoms, the medical treatment described should be instituted. If this fails, operative procedures for cure may be considered.

As regards the treatment of cases of this type, that is, conditions of adhesions affecting the gut giving this special type of symptomatology of alternating constipation and diarrhea, it may be said that the general principle is the promotion of undelayed progress of the intestinal contents throughout the course of the alimentary canal, and the consequent prevention of stasis or stagnation. The details of the treatment are not necessarily in all cases the same. In these two cases the agent which was used successfully to promote regularity of action of the intestines was agar agar. This acts primarily by giving bulk to the intestinal contents and thus promoting peristalsis by natural means similar to the action of plentiful food residue. It does not act as a cathartic drug in the ordinary sense of the term, that is by stimulating peristalsis, by unnatural action upon the walls of the intestine, or by causing an unnatural or liquid condition of the feces.

Promotion of active peristalsis or excessive movement of the intestinal contents by means of real cathartics is not in my experience a successful means of cure in these conditions; at all events not as successful a means as the use of agar or of some therapeutic agent acting along similar lines. In the first place they are apt to cause continued looseness even if ileo-stasis is prevented. Secondly, they act more upon the colon than upon the region of the lesion. Case two, as you remember, had been subjected to a course of cathartic administration for a considerable period before I saw him, with no improvement in the condition.

The same statement may be made in regard to the use of enemata for the treatment of this condition. These agents may prevent constipation in the sense that they ensure regular defecation. But they do not in all cases promote regular movement of the intestinal contents in the region of the lesion, which is frequently too high up to be affected by them. They simply clear out the lower bowel, leaving the ileo-stasis as before. They may work where the adhesions or dilatation of the gut is situated in the transverse or descending colon. But at best they are a cumbersome and artificial means of treatment as compared with the agar.

Many cases of this type do not show actual constipation in the sense of absence of a daily movement. The constipation is higher up than the colon.

In the considerable number of cases of this type which I have treated successfully by medical means, I have found the administration of agar agar the most universally serviceable of any one means of achieving relief of symptoms. It can be taken continually over long periods of time without necessity for increase or dosage such as is seen in the use of cathartics, and cannot be said to inculcate a habit save in the sense that the use of foods with large residue, fruits, etc., may be said to cause a habit. Often it may be necessary at the start of treatment to use a cathartic or enema, but this should be discontinued after a few days.

In some cases of this condition other means of promoting regular intestinal action are equally successful, or even more successful. Some cases show complete relief under the use of Russian oil or other paraffin oils; others do well under a

system of massage or of exercises devised to promote action of the abdominal muscles. In some cases a combination of all these agents is necessary.

A considerable number of these cases do not yield to any form of medical treatment. In such cases surgical interference for the removal of adhesions, or short circuiting of the intestine may result in cure.

Case 3 represents another type of intestinal disturbance associated with this same underlying condition of adhesions involving the gut.

A. M. Age 25. Date of visit March 20th, 1913. For 8 to 10 years the patient has been troubled with diarrhoea. The trouble has been present to some extent almost continually during the time. Most of the time there are three to five movements daily, loose in character. There is no special pain associated with the trouble save some colic just before a movement, but often there is a sense of discomfort in the lower abdomen associated with excessive rumbling of gas.

Occasionally the patient will have a period of three to five days when there is but one movement daily, sometimes a formed movement. Very rarely this has occurred for as long a period as two weeks. Following such periods the patient almost invariably has a period of excessive diarrhoea starting with fifteen to twenty movements daily and gradually getting down to three or five a day. The periods of looseness last three weeks to two months. Rest in bed in such periods may reduce the number of movements to one or two a day but then diarrhoea always returns upon resumption of regular manner of living. The patient loses and gains weight in turns but never weighs as much as she should. She is not very strong but her general condition is not as bad as might be expected with such a history. She is able to work except in the periods of very severe diarrhoea. There is no history of symptoms at any time suggesting an attack of appendicitis. No typhoid.

Examination: The patient is thin but fairly nourished. Haemoglobin 90%. Blood examination otherwise negative. Temperature normal. Pulse 80. Heart and lungs normal. Abdominal examination negative except for a slight tenderness in the right iliac fossa.

Examination of Faeces. Stool loose, about the consistency of porridge. No mucus, pus, or blood present. Blood test negative. Food elements present in increased amount but no excess of any one form, suggesting a specific fat or cellulose diarrhea.

The patient was advised to have an x-ray examination of the abdomen. In the meantime she was placed upon a regime consisting of a low refuse diet consisting of meat, and toast without butter, and the administration of bismuth. Under this regime, according to reports by letter the condition continued unabated. For a day or two under the bismuth there would be one daily movement but this was always followed by excessive diarrhoea. For some reason the x-ray examination was deferred.

April 10th the patient reported that for two days she had had a good deal of pain in the right iliac region and some nausea, but no vomiting. The bowels were loose as usual.

Examination at this time showed marked tenderness in the right iliac fossa with, however, no palpable mass. Temperature 100. Pulse 100. Blood showed a white count of 12000 per cmm.

The patient was placed in bed. The temperature remained between 99 and 100.5 for four days, then subsided to normal. The tenderness decreased but never wholly disappeared. This represents the first record of any disturbance suggesting appendix trouble in the history of the case.

Following this the x-ray examination with bismuth was made. It showed evidence of adhesions in the region of the caecum. The caecum was firmly bound down and immovable. The bismuth could be seen by the fluoroscope examination to pass freely back and forth through the ileo-caecal valve as if the valve were continually open. There was no ileo-stasis and no marked caecal stasis.

The explanation of this case as deduced from this record appeared to be the following:—As a result of an attack of appendicitis which occurred perhaps 8 to 10 years ago and was unrecognized, adhesions were formed binding the caecum and so affecting the gut that the ileo-caecal valve was not properly closed. April 10th, 1913, a slight recurrence of inflammation in this region occurred. As a result of this abnormal condition in the region of the caecum the contents of the intestine passed continually through the valve in both directions, thus keeping up a nearly continuous diarrhoea.

The patient was operated upon June 25th. The finding at operation was as follows:

A nearly obliterated appendix bound down by adhesions. Adhesions about the caecum binding it firmly to the peritoneal wall and apparently pulling upon the region of the ileo-caecal valve in such a manner as to keep the valve open.

The appendix was removed and the adhesions were separated to obviate all distortion and fixation of the caecum. Since operation there has been up to the present date, Jan. 1, 1914, complete freedom from diarrhoea.

This case differs from the first two in that the symptomatology was one of continuous diarrhoea rather than alternating diarrhoea and constipation, and that physiologically excessive peristalsis of the contents through the ileo-caecal region, rather than retardation, was present.

This case showed a symptomatology, continuous diarrhoea, less common in association with adhesions affecting the gut, than that found in the first two cases, alternating constipation and diarrhoea, but still not uncommon as an associate of this condition.

Apparently the effect of the adhesions in the case, as revealed both by x-ray examination, and examination at operation, and as suggested by the symptomatology, was to increase the activity of the movement of the intestinal contents, in marked contrast to the condition in the first two cases, where the effect was to retard the proper movement of the contents. Whether this result was due to actual distortion of the valve, or to spasm or reflex action I cannot say. At operation the valve appeared to be open.

I have seen several cases of this type showing an open ileo-caecal valve as revealed by x-ray examination, both under administration of bismuth by mouth, and by the use of bismuth enemata. Some of them show caecal- and ileo-stasis of bismuth in spite of the open valve, while some, like this case, show no stasis. Most

of them showed symptomatology of more or less continuous diarrhea except when kept in bed, as contrasted with the alternating constipation and diarrhea, or the continued constipation seen in the majority of cases of adhesions affecting the caecum or colon.

CASE 4 is an example of adhesions involving the intestine, giving a symptomatology of stomach disturbance, rather than intestinal disturbance as seen in the cases already reported.

Aged 55. Date of visit October 26, 1912. For a year or more the patient has suffered from dyspepsia. Two or three hours after meals he has a gnawing sensation in the pit of the stomach, associated with the belching of gas. There is no acute pain, no pyrosis or vomiting, occasional heartburn. The distress comes late in the forenoon, in the late afternoon, and sometimes at bed time, also at times in the early morning before breakfast. The taking of food, even of a few crackers, always relieves it. There is no distress immediately after meals, in fact, as stated, meals relieve symptoms. The spells of trouble are intermittent. He may be entirely free from symptoms for four days to a week and then have symptoms daily for one to three weeks. The bowels are regular. There is no appreciable loss of weight, but the patient has become very nervous and does not feel up to the mark as before this trouble began. There is no history of a former attack of appendicitis or of typhoid.

Examination. Well nourished. Haemoglobin 100%. Heart and lungs normal. Abdominal examination normal.

The fasting contents of the stomach obtained by tube twelve hours after the previous meal, a full dinner, gave the following findings: Amount 55 cc. Clear and watery, with slight sediment consisting, as seen under the microscope, of a considerable number of starch granules and fat drops. Free HCl was present. Blood test negative. Test meal contents obtained one hour after Ewald meal showed a total free HCl of 0.28%—that is, an excessive amount of acid.

The faeces gave a negative blood test upon several occasions. Stools were of normal size and character.

The results of this special examination of the stomach, together with the symptoms, suggested the presence of some lesion causing some constriction or spasm of the gut at or near the pylorus, or in the duodenum. The symptoms could have gone perfectly well with a simple hyperacidity, but the presence of 50cc. of acid contents, a hypersecretion, with an abnormal amount of food residue, as microscopically observed, a slight stasis in the stomach, suggested the existence of either an old ulcer in the duodenum or of some other cause, resulting, either by actual constriction or by reflex action, in the undue accumulation of gas, and possibly at times, of acid contents in the stomach.

X-ray examination showed

1. A marked six hour bismuth residue in the stomach.
2. Pyloric sphincter and duodenal cap well defined but dilatation of upper portion of duodenum apparent.
3. Nine-hour ileo-stasis, and evidence of adhesions about caecum.

From the combined findings an absolute diagnosis of some process causing a tendency to backing up of contents in the stomach, and a probable diagnosis of old duodenal ulcer as the underlying process, was made. Medical treatment was tried for a considerable period, as the tendency to stasis in the stomach was so slight that it was hoped it could be overcome by a proper method of dieting and hygiene. Improvement in symptoms but not cessation occurred. The case was then operated upon.

The findings at operation were:—

1. Adhesions between the duodenum and right wall of the abdomen. Some dilatation of duodenum above adhesions. No ulcer was found.

2. Evidence of a former appendicitis with adhesions about cecum.

The patient at the present time, six months after operation, has a complete absence of symptoms.

Note that in this case there was in the clinical findings, the findings by tube and the x-ray findings, evidence of disturbance of the function of the stomach in emptying its contents within the normal period, although by the finding at operation it was found that the adhesions present caused no actual obstruction of the pylorus or pulling or distortion of the stomach.

This is an example of what I have already described as the reflex action, of adhesions involving the gut, the setting up of disturbance of function, stasis and hyperacidity, and of subjective symptoms, in a portion of the gut in a region removed from the actual point of the adhesions, with no actual distortion present in the former region.

Six-hour gastric stasis of bismuth, less commonly twelve-hour stasis of food contents, are not infrequently found in cases where the adhesions are confined entirely to the cecum. In some cases such adhesions, though located far from the stomach, do by their dragging of the viscera out of position, cause some actual distortion of the stomach, or disturbance of its function, by actual mechanical effect. It is thought by some that ileo-stasis with consequent dragging down of the viscera by the load may sometimes do this. But in this case, as in several others, the stasis in the stomach appears to have been reflex from the action of the adhesions upon peristalsis lower down.

CASE 5. F. P. Age 38. Date of observation Nov. 9, 1912.

History. Five years ago the patient was operated upon for an acute attack of appendicitis. About one year after this he began to notice a heavy feeling in the epigastrium coming soon after eating. This was not present every day but bothered him off and on. One year ago the stomach symptoms became much more constant and troublesome. Distress soon after eating was often very marked. There was accumulation of gas in the stomach with distention and relief by belching at times. Six months ago the patient was jaundiced for a period of two months. At present he suffers from dyspepsia most of the time, is afraid to eat, and has lost fifty pounds

in weight. His bowels are regular. He has never vomited.

Examination. Haemoglobin 90%. Fasting contents of stomach, 10 cc. No food. No blood. Inflation shows size and position of stomach normal. Test meal contents. Free HCl=.05%.

X-ray examination. Peristalsis of stomach normal. No 6-hour bismuth residue. Caecum firmly held down by adhesions. Stasis of contents in ileum and in caecum. Operation showed adhesions fixing the caecum, adhesions extending from caecum and ascending colon to gall bladder and involving the region of the common duct and portal vessels.

January 1, 1914. Since the operation the patient has been free from symptoms.

In this case the symptoms, with the exception of the jaundice, were mostly those suggesting stomach disturbance. No evidence of actual stasis in the stomach, as in the last case, was found. It is true that the symptoms of distress, and of accumulations of gas, complained of by the patient, and laid by him in his stomach, may have been pain and accumulation in the intestine. But at all events the history was one of stomach disturbance.

SERODIAGNOSIS OF PREGNANCY. A REVIEW.*

By A. K. Paine, M.D., Boston.

One of the striking recent advances in obstetrics has been the formulation of the serodiagnostic test of pregnancy.

Needless to say, the diagnosis of the existence or non-existence of pregnancy is a factor of considerable importance in obstetrics, and it is true, as with many other things in the practice of medicine, that its solution depends almost entirely on individual judgment, subject to all the uncertainties and errors which attend such efforts. That individual skill and much experience increases the percentage of opinions that later prove to be correct is also true, but opinions only they remain until proved or disproved.

The wonderful advances made during the last two decades in the practice of medicine are the result largely of the illumination here and there of its mysteries by the bright light of scientific accuracy emanating from the modern medical laboratory. That this irregular illumination discloses complexities beyond even our imaginations only emphasizes the utter darkness in which we have struggled.

For the first time it seems a possibility that the subject under discussion may be lifted from the plane of conjecture to that of accuracy. Various attempts have been made to develop some method whereby the diagnosis of pregnancy could be accomplished by enlisting the aid of the laboratory; the antitrypsin test as carried out by Franz, Jarish, Rosenthal and Jochmann was one of these, a marked increase in the antitrypsin index indicating pregnancy, but as such an increase is also observed in a great number of diseases and disorders, its value as a diagnostic aid was nil. The complement fixation test of Fieux and Mauriac is open to the same objections, while the epiphanin reaction of Mosbache and the adaptation of the miostagmin reaction by Julchiero are impracticable and not confirmed.

It remained for Emil Abderhalden, director of the Institute of Physiology at the University of Halle, to offer a method whereby the diagnosis of pregnancy may eventually become a procedure of scientific accuracy.

This procedure is based on certain facts which have been disclosed by researches in the biochemistry of protective ferments. It has been demonstrated that substances containing elements common to body tissues, but of a different formation are, when introduced into the body, altered by various processes until their composition corresponds to that required by or acceptable to the body. The digestive process itself by which food is converted into body tissues represents perhaps the most commonly considered type of this procedure. Further, if these foreign substances are introduced directly into the blood there is created in the blood an agent described as a protective ferment, which attacks the foreign substance, reducing or changing it to substances tolerated or acceptable to the organism. Again, and of even greater interest and importance, each specific substance which may be introduced causes the formation of a specific protective ferment which attacks that substance, but no other. It is along these lines that Abderhalden has been working, and some of his experiments are extremely interesting.

If the serum of a dog is placed in a polariscope together with cane sugar no rotation occurs, indicating that there is no cleavage between the two, but if the dog's blood has first received an injection of cane sugar, that serum placed in a polariscope with the sugar exhibits rotation or cleavage, indicating that there was developed in the dog's blood as the result of the presence of the foreign matter, sugar, a substance which has the property of attacking sugar, changing its structure to one acceptable to the organism.

Abderhalden has further shown that substances natural to the body are foreign to the blood when introduced directly into it, causing the appearance therein of specific protective ferments. For instance, kidney tissue, or cells introduced into blood cause the appearance of ferments which are specific for such tissue, and further that such ferments are specific for the kidney tissue from other dogs as well. Another fact on which this procedure was based was the demonstration by Schmorl, Veit and Weichardt, that shortly after pregnancy begins and continuing for some days after its termination, chorionic epithelial tissue or cells from time to time enter the maternal circulation. Abderhalden was able to demonstrate that these chorionic cells

* Read before the Boston Surgical Society, Dec. 18, 1913.

in the blood stream gave rise to the formation of a specific protective ferment which attacks these cells, causing them to lose their individuality, becoming thereby acceptable to the blood, and Abderhalden's serodiagnosis of pregnancy consists in the demonstration of these protective ferments in the blood of a pregnant woman. The demonstration itself consists in showing that the serum of a pregnant woman will react on placental tissue, *i.e.* chorionic cells, outside of the body, owing to the presence in the serum of these ferments with a predilection or specificity for chorionic tissue, these ferments being developed in the blood of the pregnant woman to combat the invasion of its stream by chorionic cells, an occurrence continually happening, as shown by the work already mentioned, and corroborated by the investigations of Peters, Strahl, Beneche, Brice, and Teacher, who further showed that these cells are present in the blood stream as early as the first month of pregnancy. With these chorionic cells in the maternal blood, protective proteolytic ferments are mobilized which will cause cleavage of human placental albumen and its reduction into peptones and amino acids. Abderhalden states that there is in all probability a much greater exchange of substances between the placenta and the maternal blood during pregnancy than simple chorionic cells, which opens up a field of vast possibilities in the investigations of the various phenomena of pregnancy, particularly with reference to the so-called toxemias which may represent some disturbed balance between the entrance of various substances foreign to the blood and the production of the protective ferments to combat such an invasion. The study of the protective ferments offers an alluring prospect in other subjects than obstetrics, the work of Fuchs being especially interesting. He reports experiments which confirmed the absolutely specific nature for the organ involved of the ferments demonstrated by the Abderhalden technic. The serum of rabbits treated with human kidney tissue was able to digest kidney tissue in eighty-eight hours, while it did not digest liver tissue, and vice versa. He has also confirmed in further research the findings of others in regard to the specific digestion of testicle tissue by the serum of men with dementia precox and of ovary tissue by women under similar circumstances, but never the reverse. Also the total absence of any digesting property for the ovaries or testicles in the serum of patients with depressive mania, and further, the positive reaction in cancer cases. The reaction proved specific for the organ whether derived from human beings, calves or laboratory animals, and it was equally pronounced irrespective of the species.

The diagnosis of pregnancy by demonstrating the presence in the blood of a proteolytic ferment specific for placental albumen, as can be imagined, is a complicated procedure necessitating laboratory technic of a high grade. Abderhalden has from time to time changed, improved, and simplified his technic, all the while insisting upon the necessity of an absolute regard for the most minute details of the work. That other investigators were, especially in the beginning, unable to secure the same results as he himself did he attributes to errors in technic, and that most investigators appreciated this fact is witnessed by the character of their work, which improved as they eliminated the various sources of error. To illustrate the ease with which the results may be negated, one instance might be cited. Two investigators, Schimpert and Hendrey, working in Freiberg, were unable to substantiate Abderhalden's results. They went to Halle and worked in his laboratory perfecting their technic, but on returning to Freiberg again failed with their tests, when investigation soon disclosed the fact that the water of Freiberg, which was used to wash the placental tissue, was so soft as to cause a hemolysis of the blood in the placenta, resulting in a contamination of their material, and so a distortion of their results. Correcting this difficulty by the addition of salt to the wash water, they were then able to duplicate Abderhalden's work. Without reviewing the earlier technic of Abderhalden, in which a special polariscope was used to demonstrate cleavage between placental tissue and serum containing the specific proteolytic ferment, a brief description of the technic as employed at the present time may be given,—the so-called dialysation method. The theory and procedure by which the serodiagnosis of pregnancy is made may be first very briefly stated. The serum of a pregnant woman contains a specific proteolytic ferment, which has the power to digest placental albumen. Pregnancy can be diagnosed by demonstrating the presence of this ferment in the blood serum. Its presence in the serum can be shown by the addition of such a serum to placental albumen, resulting in a digestion of the albumen.

The serum is removed from a few c.c. of blood taken from a supposedly pregnant woman; this added to a small amount of thoroughly washed human placental tissue, is placed in a parchment bag (called a dialyser); the bag is then immersed in distilled water contained in a glass dish, the whole being incubated for a proper period. At the end of this period if the serum contains the proteolytic ferment present in the blood of a pregnant woman a more or less complete digestion of the placental albumen will have occurred. The parchment bag has the peculiar property of retaining albumen, but of allowing the products of albumen digestion to escape, that is, its walls are impervious to colloid substances, as albumen, or serum, but are pervious to crystalloid substances, as peptones, amino acids, etc, *i.e.* the end products of albumen digestion. So if any digestion of the placental albumen in the bag occurs as the result of the presence of a specific proteolytic ferment in the serum which was added to it, some of the products of its digestion

will escape from the bag into the surrounding sterile water, where their presence is determined by a delicate reaction in which a substance ninhydrin is used. This latter is a salt, which added to a solution containing peptones, polypeptids or amino acids gives a violet color on boiling, even though the amount of these end products of albumen digestion be exceedingly small.

While the theory of the procedure is comparatively simple, the actual practise of the test demands a high grade of laboratory skill and a most painstaking regard for the minutest detail. The following description of the test is as brief as is compatible with accuracy.

1. *Serum.* Thirty c.c. of the patient's blood are withdrawn from one of the superficial veins at the elbow, using a glass syringe of the type employed for antitoxin or serum administration. Needless to say, strictest aseptic technic is required. The serum from this blood should be used the same day, and it is important that it be free from corpuscular elements, bacterial contamination, and that no hemolysis has occurred.

2. *Placental Albumen.* This is obtained from fresh normal placentas, from which the membranes and fetal surfaces are removed. The placenta is cut in portions the size of a twenty-five cent piece and washed in running water to remove blood. It is then boiled in water containing two drops of glacial acetic acid to each two litres for five minutes in a porcelain dish; it is then boiled in a fresh water for another five minutes, when the water is tested after filtering for albumen, using the ninhydrin test. If the test is positive the placental tissue is boiled again and repeated until the filtered water is negative for albumen. The coagulated albumen, together with the last water, is placed in a glass jar and covered with a layer of toluol, the latter a balsam preparation which acts as a cover to prevent contamination of the contents of the jar. It is now ready for use, but should be tested on each occasion it is used, if more than one day elapses between tests. The important thing is to be sure that it is free from all dialysable substances, as peptones, alpha amino acids, etc.

3. *Dialysers.* The dialysers are porous parchment bags, those made by Shleicher and Schnell, No. 579A, being the most satisfactory. Each bag must be tested for the permeability of peptones and the non-permeability of albumens.

To test for permeability of peptones, 5 c.c. of a 1% solution a "Seiden" peptone with 20 c.c. of sterile water are placed in the bag and incubated for 16 hours at 29°C. The dialysate is then tested for peptone with ninhydrin; a moderate color indicates that the dialyser is suitable, a weak or strong color indicating that the dialyser should be discarded.

To test for the non-permeability of albumen, a solution of egg albumen is placed in the bag, and after incubation the dialysate is tested for albumen, a negative result indicating that the bag is a suitable one. After these tests the dialysers are washed and boiled, and then kept in chloroform water covered with toluol. They are washed and boiled after each test, and should be from time to time retested for permeability as indicated above.

4. *Ninhydrin* is the trade name of Triketohydrindenhydrate, a salt discovered by Ruheman, which when added to a solution containing albumen, peptones, polypeptids, or the amino groups in the alpha position to the carboxyl group gives a violet color on boiling. It is much more delicate and sensitive than the well known biuret reaction.

The fact that "ninhydrin" reacts with protein derivatives which no longer give the delicate biuret reaction, has made it doubly useful in following the transformations of the albuminous substances into their non-protein components. In order to ascertain to what extent abiuret compounds, which react with triketohydrindenhydrate, though they do not give the classic biuret reaction, may be distributed in the organism, Abderhalden and Schmidt have made an extensive search for such reacting substances. These were duly found existent in fresh milk, urine, saliva, blood-plasma and serum, lymph, sweat, the contents of cysts, egg, and meat, and it is necessary in the execution of tests involving the use of the reagent, to employ special precaution against contamination with skin secretion, small traces of which are sufficient to initiate a positive reaction.

As the result of applying the new ninhydrin test, Abderhalden has already found that certain biologic reactions, hitherto ascribed to the proteins, are associated with the presence of biuret contaminations which give the reaction. Thus it appears that various proteins which provoke distinct physiologic responses when introduced into the body lose this property if they are first purified by dialysis until the compounds reacting with ninhydrin completely disappear. The bearing of this on the study of anaphylaxis will at once be apparent. Abderhalden insists that all proteins employed in anaphylactic investigations must be subjected to thorough purification by dialysis before the responses which they may elicit are charged to the protein itself rather than to derived products accompanying it.

5. *Containers* should be of glass, sterilized, and should be of sufficient size so that there will be 1 c.m. between the walls of the container and the dialyser when the latter is placed in the container.

Technic of the Test. A dialyser previously tested as described is removed from the chloroform solution and washed. In it is placed one gram of the placental albumen, which is free from all dialysable substances. To this is added 1.5 c.c. of serum from the supposed pregnant case, after which the dialyser is washed in running water to remove any possible albumen contamination from its outer surface. It is then placed in the container with 20 c.c. distilled

water; the top of the water should be 25 cm. above the top of the dialyser contents and covered with a layer of toluol. The container is closed with a sterile cotton plug and placed in an incubator at 37.5° C. for 16 hours, at which time the dialysate is tested for the presence of the products of albumen digestion. Ten c.c. of it are taken free from toluol and placed in a small beaker. To it are added 2 c.c. of a 1% solution of ninhydren, after which it is boiled for one minute after the first bubbles appear. The color is read after thirty minutes.

A clear or yellow color denotes a negative result. A violet, light lavender, or bluish purple color denotes a positive result.

Controls. As with similar tests, a control test is necessary to insure the accuracy of the results. Fifteen c.c. of serum alone is placed in a separate dialyser, the dialysate being tested after incubation in the same manner, or 15 c.c. of serum may be inactivated by heating at 60° C. for ten minutes, after which it is placed in a dialyser with one gram of placental albumen, incubated and tested as before.

Jellinghaus and Losee give the following as the method of interpreting a test.

Dialysate negative with ninhydrin, controls negative, not pregnant.

Dialysate positive with ninhydrin, controls positive, not pregnant.

Dialysate positive with ninhydrin, controls negative, pregnant.

Dialysate positive with ninhydrin, controls positive, but distinctly lighter in color, pregnant.

They emphasize the need of minute attention to details and enumerate those especially needing care.

1. The placental tissue must be fresh.

2. The placental tissue must be free from blood.

3. If washed in very soft water salt should be added to avoid the possibility of hemolysis. After the blood is removed with the water containing salt, further washings are with plain water.

4. The placental tissue prepared for the tests should be tested each day before use for the presence in the water of any substances giving a positive reaction with ninhydrin; should any be present it should be reboiled as described in its original preparation.

5. The dialysers should be frequently tested with albumen and peptones for permeability.

6. The serum must not be hemolyzed and must be free from dialysable substances. It should be used from two to five hours after obtaining.

7. The contents of each vial of ninhydrin should be measured, as they do not always contain a full gram. Two c.c. of a 1% solution is used; this solution will keep seven days.

8. Emphasis is laid on the need of observing strict asepsis in handling the materials for the test and on the aseptic condition of all containers and utensils.

Coming to the practical and therefore interesting and important aspect of the test, we may first admit certain facts as sufficiently proven: first, the blood of a pregnant woman contains at least one substance peculiar to the pregnant state, *i.e.* a proteolytic ferment specific for chorionic epithelium (placental albumen), and second, that it is possible to demonstrate the presence of this substance by a bio-chemical test. The questions that immediately arise are: Is the test practical from the point of view of ordinary laboratory technic? Is it reliable? Can it be useful in the general practice of obstetrics? Or is it only of ultra scientific interest, a by-product of the research laboratory? The questions can best be answered by a generalized review of the work of the various investigators of its merits. That it has awakened much interest in the scientific world is evinced by the volume of literature on the subject published since Abderhalden's first reports in 1912. It is interesting and natural perhaps that the greater portion of articles concerning it are of German origin; next to Germany this country has been most prolific in its contributions. There have been reported in all considerably over two thousand cases in which the test has been applied. A study of these reports indicates several striking facts: first, that the reports of the early tests of the various investigators show a much higher percentage of failures than the more recent works of the same investigators and that the earlier failures were almost invariably because of faulty technic, a fact testified to by the authors themselves. Second, that the enthusiasm for the accuracy and practicability of the test increases rather than diminishes with the increasing familiarity with its details as acquired by the men engaged in the work.

It may be stated that there is almost an unanimity of opinion that the test is accurate in results and practicable in performance. Some investigators have questioned, however, the specificity of the ferment, their results seeming to show that positive reactions are possible with other conditions than pregnancy. For instance, Williams and Pearce state that it was never negative with a known case of pregnancy, but was also positive in two cases of nephritis, one of tabes, one of infectious carbuncle, and occasionally in perfect health. On the other hand, Schwarz vehemently attacks the work of Williams and Pearce, declaring their technic faulty and intimating that they don't appreciate what hemolysis means. Lindig, another who said the reaction was positive in other conditions than pregnancy, especially cancer, is taken to task by Abderhalden who says Lindig's errors are to be found in the use of a powdered placental preparation, the latter almost invariably giving a positive reaction, especially if kept for any time, the result apparently of some decomposition process which forms dialysable substances. Veit says

the test is a valuable one and brings up the point that the ectopic pregnancies do not react positively, probably because the chorionic cells are thrown off with the tubal abortion. Henkel, Sutman and McCord commended the test, McCord wth 240 cases and practically no failures. Abderhalden reports 200 cases with one failure. Jellinghaus and Losee report 563 cases, grouped according to the various stages of their technic, concluding that it is an accurate test for the presence or absence of chorionic cells still capable of being washed into the maternal circulation. Petri says it is amazingly accurate. Wolff describes his experiments, resulting in failure until he learned from Abderhalden himself the exact technic for preparing the placenta. He concludes that the method shows pregnancy in its very beginning and that the reaction is of special value for differential diagnosis between pregnancy and tumors. He says the test is not suited for general practice, but has great value in hospitals, where it can be performed often enough to ensure exact technic. Gambaroff reports from Moscow forty-eight cases of cancer and thirty-seven other cases in which the Abderhalden technic was applied, including twenty-two pregnant women and ten normal persons, the tabulated details showing remarkable concordance, constantly negative responses in the normal serum and constantly positive in all the others, with the single exception of a syphilitic who gave a positive cancer reaction. Judd says: "Some thirty or more of my own cases tested by this method have been quite in accord with the strict specificity of this test when putrefactive changes, fresh serum, and the proper selection of dialyzers have been carefully controlled." On the other hand, Heaney and Davis say a review of the literature and an experience with the test, together with the use of other means of testing the digestive activity of the blood, leads the authors to question the specificity of the test of Abderhalden; though since the need of such a reaction is great they urge that the test should be further tried and its results reported accurately. Schwarz suggests an error in technic to explain the failures. Echols says: "Fifty-seven tests were made according to Abderhalden's method; though the test will probably never be simple enough for the general practitioner to carry out, there is reason to believe that when done in properly equipped laboratories, Abderhalden's method will in the course of a year or so take its place with the Wassermann and Widal reactions in point of reliability." Ruhsamen reports ideal results in one hundred cases. Liehenstein, forty positive results in forty pregnancies, one positive result in thirty-four non-pregnant cases. Zoeppritz describes early failures, but with a mastery of technic perfect results in fifty cases. Engelhorn does not consider Abderhalden's dialysis method a specific reaction as a diagnosis cannot be reached by it, but there is some question of the accuracy of his technic. Mayer considers Abderhalden's pregnancy reaction a valuable aid to diagnosis. Schufer had two incorrect results in one hundred and twenty-three tests. Strange states that positive findings were obtained in 100% of the seventy-three women tested with Abderhalden's technic.

I am fortunate in being able to describe some results obtained here in Boston. These are from a series being prepared for a future report by Dr. W. H. Grant, the laboratory work being done by Dr. McCarthy of the pathological department of Tufts.

In twenty cases known pregnant, the first seventeen were positive by the Abderhalden technic, the last three negative, these accompanying difficulty with the dialysers. Eighteen cases clinically pregnant gave positive results in each case, four cases not pregnant gave four negative results. Besides these were twenty-eight tests in doubtful cases giving varying results, but which until sufficient time has elapsed to demonstrate the presence or absence of pregnancy, have no significance. The report of the completed series will be awaited with interest; in the meantime one is impressed by the concordance of the clinical and laboratory findings.

From a review of the literature one may draw several conclusions:

1. That the study of the bio-chemistry of the protective ferments is one destined to be of great importance in solving many of the hithertofore unexplained phenomena of health and disease.

2. That pregnancy aside from its local manifestations, evinces at least one general effort on the maternal organism similar to that evinced by pathological conditions, *i.e.* causing an invasion of the blood by elements foreign to it, and that there are developed in the blood substances to combat this invasion much in the same manner as the invasion of disease is combated, bearing out the tendency in evidence of late, to regard pregnancy as a pathological condition.

3. That although the Abderhalden test for the presence of the specific proteolytic ferment present in the blood of pregnant women is a difficult and extremely delicate one, a really surprising number of accurate results have been reported, especially surprising when considering that these reports are from a great number of widely separated and independent investigators, each of whom had to perfect his individual technic to a certain extent before it could be said that the theory and not his skill was being tested.

From which may be made the following deductions:

1. That the test is available where the services of a competent laboratory can be had.

2. That it is by far the most accurate method at our disposal for the diagnosis of pregnancy, comparing favorably as a test with the Widal and Wassermann reactions, in their respective fields.

3. That until some method is devised whereby the materials used, especially the prepared placental albumen, may be kept for some time

and in a more convenient form, and dependable dialysers more easily procurable, the test will not be generally available.

In this connection it may be mentioned that attempts are being made to simplify the technic so as to make it more generally available. Gutman, in a personal communication, expresses confidence that such a simplification can be accomplished, difficulty in procuring a special dialyser being the particular obstacle with which he is contending.

4. That it places in our hands a possible means whereby we may make a remarkably accurate diagnosis of the existence or non-existence of pregnancy, should the exigencies of any case demand a prompt determination of the fact.

THE EFFECT OF "606" ON THE EYE, WITH THE REPORT OF SEVEN CASES OF SERIOUS EYE COMPLICATIONS FOLLOWING ITS USE.*

BY P. S. McADAMS, M.D., BOSTON.

Physician to the Eye Department of the Boston Dispensary.

WHEN Ehrlich first introduced his 606 there was a great fear in the minds of the ophthalmologists that the effects of the new preparation on the eye would be similar to that produced by other arsenical compounds such as atoxyl, arsacetin, and soamin, which had preceded it. All of these arsenic compounds had been claimed by their introducers to be harmless to the eye, but further experience proved this not to be the case. Quite a large number of cases of blindness were reported to have followed their use. Of these preparations, the one most largely used was atoxyl, an empirical, synthetical arsenic compound, which came into use in the treatment of sleeping sickness and was used to a considerable extent in the treatment of syphilis. Although, claimed at first to be innocuous to the eye, from a study of the literature for 1908, 1909, and 1910,—the years during which it was chiefly used,—I have been able to find over 100 cases of complete blindness and a large number of cases of partial blindness resulting from its administration. The ocular manifestations following its use always assumed the character of a primary optic atrophy. It was essentially a degenerative process affecting either the ganglion cells of the retina or the fibres of the optic nerve, somewhat similar to the condition produced by other toxic substances, such as methyl alcohol, quinine, and other toxic substances. Both eyes are invariably affected. The blindness may come on suddenly or gradually, but once the lesion is produced, it remains stationary or slowly progresses until more or less complete blindness results. A partial recovery occasionally occurs if the drug is withdrawn early enough. The condition is not improved by any treatment, and a second injection of atoxyl never improves vision, but causes a more profoundly injurious effect. With the ophthalmoscope the picture is seen to be one of simple optic atrophy.

The attitude of the ophthalmologists towards 606 was well expressed by Henderson, of St.

* Read at the October, 1913, Clinical meeting of the Staff of the Boston Dispensary.

Louis, who, in an article on the effects of atoxyl, in the *American Journal of Ophthalmology*, for November, 1910, says in his concluding paragraph: "The subject is worthy of careful ensideration in view of the approaching distribution of 606. If I am correctly informed, this, too, is a synthetic preparation of arsenic. The world-wide publicity already given to the achievements of this remedy will result in its more or less indiscriminate use by every physician who can get it. In accepting and using this potent remedy we must not forget that all of its predecessors were for a time considered harmless in their action upon the visual apparatus by authorities in whom we had every right to repose the greatest confidence."

The important questions which the ophthalmologist wished to have answered were: (1) Is arsenobenzol innocuous to the healthy eye, especially the healthy optic nerve? (2) Can it be used when the nerve is inflamed? (3) Is it a safe and efficient remedy in the treatment of syphilitic disease of the eye itself?

Serious disturbances of the visual apparatus certainly do follow the administration of arsenobenzol in a certain number of cases, but when one considers the tremendous number of patients that have received it, the number of ocular disturbances following its use are small as compared with atoxyl and its allied drugs. An examination of the literature during the past three years shows that most authorities believe that the eye lesions following 606 are to be considered as relapses of syphilitic disease, and not a consequence of the arsenobenzol. There are still a few, however, who maintain that it is a menace to the eye and should be used only in special conditions. Ehrlich himself, in view of the bad results to the eye following atoxyl, advised caution in the use of his preparation and advised a careful examination of the eye before injection. Later, however, when he had received reports of a large number of cases without untoward effect upon the nerve, except in one case, he claimed that 606 was without detrimental effect upon the eye. He also deplored the fact that ophthalmologists were not making sufficient use of his preparation in syphilitic diseases of the eye. In defending the use of 606 against the charge that it was not without danger to the eye, in the *Wien. Klin. Rundschau* of Jan. 29, 1911, he states that disturbances of the optic nerve in recent cases of syphilis are found, not only after the use of salvarsan, but also after the use of Hg. On the other hand, when sufficiently large doses of salvarsan were used, such affections were never seen. The use of atoxyl and arsacetin show that the toxic symptoms increase with the amount of the dose injected. The optic nerve affected after salvarsan improves under antisyphilitic treatment, and sometimes it is cured by another injection of salvarsan. An affection of the nerve caused by atoxyl could never be cured by an additional injection with an arsenical preparation. Numerous other authors support the contention of Ehrlich that arsenobenzol is innocuous to the healthy eye, and the ocular lesions following its administration should be considered as manifestations of syphilis. Wechselmann and Selligshon of Berlin gave the injections in 1400 cases of their own, and collected reports from approximately 20,000. Of these cases, none showed any harmful effect upon the optic nerve. At first they excluded from the treatment any cases showing inflammation of the nerve, but later, after they had given the injection to several doubtful cases, that is, cases where it was impossible to say whether the nerve was inflamed, or not, without deleterious effect, they used it in several cases of outspoken optic nerve affection, with the result that the condition of the inflamed nerve was considerably improved, and in some cases cured. From this they conclude that 606 may be given with favorable results, even when optic neuritis exists. This opinion is confirmed by the experience of most writers. They also gave the remedy in a number of cases of primary optic atrophy, on which it had no apparent effect, either beneficial or otherwise. This, however, is quite contrary to the experience of others. Most authors agree that the effect of the 606 on the atrophic nerve is detrimental, that it causes a more rapid degeneration of the nerve, and that atrophy of the nerve should be considered a contra-indication for the administration of the drug.

A comparison of the lesion resulting after atoxyl with that following 606 will aid, I think, in determining whether the ocular lesions after 606 are due to the arsenobenzol or not. In atoxyl poisoning the lesion is essentially a degenerative one, resulting in an optic atrophy very similar to the condition produced by other toxic substances, whereas the lesion following 606 is an acute inflammatory one. Usually four to eight weeks, or even longer, after an injection of 606 the patient notices a sudden dimness of vision, which becomes rapidly worse. With the ophthalmoscope the vitreous will be found to contain a greater or less number of opacities which at times are so profuse as to prevent a clear view of the fundus. The disk, if it can be seen, is red and veiled, may be swollen, and the blood vessels, especially the veins, dilated and tortuous; scattered through the fundus will be found inflammatory exudates in the retina and choroid, often accompanied by hemorrhages. These are precisely the sort of lesions which appear in syphilitic disease of these structures and form a picture diametrically opposite to that found in atoxyl and allied poisoning. But one eye usually is affected,—although both may be. In atoxyl poisoning both eyes are invariably affected. Antisyphilitic treatment, or another injection of the 606, will usually improve and sometimes clear up the condition. After atoxyl no treatment benefits, and a further injection of atoxyl causes a

more profoundly injurious effect. Moreover, the late appearance of the lesion after the injection of the 606 seems to me to have a bearing upon the question of its causation. Usually it is a matter of weeks, or even months, after the injection before the ocular symptoms appear. As we know, the arsenic is rapidly excreted from the system,—usually after three to four days but few traces can be found,—and it seems to me that if toxic symptoms were to be produced they would be found shortly after the injection, while the organism was still under the influence of the arsenic.

Iritis, retino-chorioditis, optic neuritis, and ocular palsies from affection of the third, fourth and sixth nerves, as well as affection of the fifth nerve, have followed the use of salvarsan in a certain number of cases. Davids reports a case which had bilateral iritis following an intramuscular injection. Two weeks later a relapse occurred in one eye, which rapidly subsided after an intravenous injection. Van Lint reports two cases of iritis treated with salvarsan. Iritis was reproduced in the same eye after the injection. DuJardin and DeNeux have observed in two cases of secondary syphilis recently injected commencing optic neuritis, paresis of the superior oblique muscle and paralysis of the oculomotor, with beginning papillitis. They think that these conditions have a bearing on the administration of 606, but do not think it is a purely toxic action. They believe there exists a relationship between the modified syphilis and the action of arsenobenzol, causing a disturbance in the evolution of the disease. Shanz reports two cases of optic neuritis following the injection of salvarsan, which were cured by a repetition of the injection. We have had one case of affection of the fifth nerve following 606 at the Dispensary. There was anesthesia of the cornea and the right side of the forehead and the face. The lesions in the eye itself may be considered as syphiliomata produced by the immigration of the spirochetes which have been freed by the softening of foci by the injections. They are analogous to the tubercular metastases observed after the injection of tuberculin. It must be remembered that the nerves pass through narrow channels of bone lined with a tough connective tissue, which, as places of predilection for nests of spirochaetes, escape the therapeutic action of the 606. Some explain these apparent relapses as an endotoxin action, the endotoxins having been set free from the dead spirochaetes.

The relapses following 606 were much more frequent in the early days of its use, when there was more or less uncertainty in regard to the size of the dose, and the hope was entertained that it was the *therapia sterilans magna*, which would cure by a single injection. As a result, the amount given was too small to kill all of the spirochaetes, and those not destroyed were later able to cause relapses of the disease in various tissues. Moreover, it is held by some authorities that small doses have a provocative or irritative effect. According to Ehrlich, in such cases the parasites are not killed, the dose being too small, but irritated and in this condition produce greater quantities of toxins. At any rate, during the past year, during which the drug has been administered much more energetically, relapses in the eye have not been so frequent.

It has been the custom at the Dispensary to refer those cases which were to receive 606 to the eye room for examination, especially with reference to the condition of the optic nerve and the fundus. A report is returned, giving the vision of each eye and the condition of the fundus and optic disk. If the vision of either eye is below normal, the reason for the same, refractive error or otherwise, is stated. A record of the same is kept both in the skin room and in the eye room. We thus have an exact knowledge of the condition of the eye before the injection of salvarsan, and if a deterioration of vision should occur subsequently the case is referred again to the eye room for examination as to its cause.

During the past year, from July 1, 1912, to July 1, 1913, arsenobenzol has been administered, by a coincidence, 606 times. We have the records of four cases in which disturbances of vision followed the injection during this period. In addition to these four there were three other cases which received the injection just previous to July 1, 1912, but whose eye symptoms appeared or were treated after July 1, and these we have included in this group. It will thus be seen that but two-thirds of one per cent. of the cases receiving the injection show disturbances of the eye afterwards.

Of these seven cases, six showed serious lesions of the deeper structures of the eye, and in four of these practical blindness has resulted. In one case the relapse showed itself as an iritis, which readily improved after a second injection of arsenobenzol. In analyzing these cases, the important data are:—

1. The date of the injection.
2. The date of the onset of symptoms.
3. The character of the lesions in the eye; and
4. The result of treatment and prognosis;

and it is with a view to these headings that I wish briefly to describe these cases:

CASE 1. Man, 41 years of age.

(1) *Date of Injection of* 606. First injection Sept. 7, 1811. Second injection, February 20, 1912. Both eyes normal.

(2) *Date of Onset of Symptoms.* April 16, 1912, over six weeks after injection. Vision of right eye = 10/200.

(3) *Character of Lesion.* Numerous opacities of vitreous, disk blurred and veiled, several hemorrhages and exudates in chorioid and retina.

(4) *Treatment and Result.* In spite of energetic antisyphilitic treatment vision rapidly failed. At last examination, Sept. 26, 1913, vision = could

count fingers in temporal field. With the ophthalmoscope, vitreous opacities still present but not nearly so numerous, hemorrhage on disk—atrophic patches through fundus.

Case 2. Man, 27 years of age.
(1) *Date of Injection.* June 5, 1912. Eye normal.
(2) *Date of Onset of Symptoms.* Six weeks later noticed blurring of vision of left eye—vision = 20/80.
(3) *Character of Lesion.* Dust-like opacities of vitreous, disk swollen and red, veins engorged and tortuous—exudate in chorioid and retina.
(4) *Treatment and Result.* Intramuscular injections of mercury. Vision failed rapidly for a month at which time V = 4/200. Went to New York, treated there by a physician with pills and drops. Vision improved somewhat until last March when there was sudden loss of vision—no treatment since. Seen Sept. 16, 1913, when V = light perception. Received 606 again September 19,—two days later some improvement. Last seen September 30, V = hand movements at 2 m. Examination with ophthalmoscope shows massive exudates in vitreous obscuring all details of fundus.

Case 3. Young woman. Grace G. 22 years. Referred to eye room for specific iritis of right eye on June 20, 1912.
(1) *Date of Injection.* June 26, 1912. Vision of OD = 20/40. Vision of OS = 20/20. Fundus O.K. Iritis rapidly improved.
(2) *Date of Onset of Symptoms.* Six weeks later right eye became affected. Seven weeks later left eye became affected.
(3) *Character of Lesion.* Opacities of vitreous in both eyes—disks red and blurred.
(4) *Treatment and Result.* In spite of most vigorous antisyphilitic treatment together with pilocarpine sweats and subconj. injection of Dionin 10%, her vision rapidly grew worse and at the end of four months she had to be led to the dispensary for treatment. On Jan. 13, 1913, about five months after onset of symptoms, her lids became enormously swollen, red, tender and indurated so that she was unable to open them. A tense, tender swelling could be felt along the upper edge of orbit on both sides = orbital periostitis. Vision = hand movement. Later showed syphilitic nodule on sclera. Under vigorous specific treatment with pilocarpine sweats gradually improved in course of next few months. Vou = 20/40, July 12, 1913. Last seen September 23, 1913. Vitreous quite clear; few atrophic spots in fundus. On posterior surface of cornea deposits of inflammatory exudate. V OD = 20/100, V OS = 20/70.

Case 4. Man, 23 years of age.
(1) *Date of Injection.* July 24, 1912. Eyes normal.
(2) *Date of Symptoms.* Two weeks later pain and redness of left eye.
(3) *Character of Lesion.* Iritis with posterior synechia.
(4) *Treatment and Result.* Received a second injection of 606 on August 28. Rapid improvement.

Case 5. Man, 42 years of age.
(1) *Date of Injection.* August 20, 1912. Eyes normal.
(2) *Date of Symptoms.* Seven weeks later vision of left eye failing. Vision = light perception only.
(3) *Character of Lesion.* Vitreous so smoky that details of fundus could not be made out. Three weeks later developed an iritis.
(4) *Treatment and Result.* Iritis improved rapidly under local treatment—atropine. Condition of vitreous remained practically the same in spite of antisyphilitic treatment. Saw him last on January 10, 1913. Vision very slightly improved. Could count fingers with OS. With opthalmoscope condition of vitreous practically the same.

Case 6. Man, age 27 years.
(1) *Date of Injection.* Oct. 9, 1912. Vision and fundus normal.
(2) *Date of Symptoms.* March 26, 1913, five months later, V OD = 20/50. Could not state just when symptoms began but quite recently.
(3) *Character of Lesion.* Large vitreous opacities—disk red and veiled. Fundus indistinct.
(4) *Treatment and Result.* Received injection of 606 without any apparent improvement. Specific treatment. Last examined May 31, 1913. V OD = 20/70. Fundus indistinct—numerous floating opacities of vitreous.

Case 7. Woman, Sarah B. Age 29.
(1) *Date of Injection.* February 12, 1913. Eyes normal.
(2) *Date of Symptoms.* Six weeks later, on March 26, 1913, returned saying vision of left eye had become dim several days before. V OS = 20/120.
(3) *Character of Lesion.* Some haziness of vitreous. Disk red and blurred—retino-choriodities in macula.
(4) *Treatment and Result.* Three days later showed beginning iritis. Specific treatment. Condition grew worse. April 2 received second injection 606, no improvement. April 17 vision = 7/200. Improvement from this time on. July 8 vision = 20/50. Last seen September 30, 1913. Vitreous clear. Few glistening spots in macula and other parts of fundus. Disk O.K. Vision = 20/30.

In analyzing these cases, the first point that strikes one is the length of time that elapsed between the time of the injection and the onset of the eye symptoms. In every one of the cases involving the deeper structures of the eye a period of at least five to six weeks elapsed before the onset of the symptoms. Surely all the arsenic had been eliminated from the system by this time. The second most striking feature is the severity of the eye lesions. In four out of six of the cases in which the deeper structures of the eye were involved practically complete blindness resulted. None responded to the ordinary anti-specific treatment. This is not in accordance with the views expressed by others who say that lesions following 606 are usually improved by specific treatment. In both of the other cases the vision was impaired, in one quite severely, a vision of 20-70 resulting. While I believe that in all of these cases the effects were due to the disease and not to the drug, it tends to prove that the character of the disease is changed, that its virulence is increased. This would support the contention of those who believe that insufficient doses have a provocative

or irritating effect. A third point is that these relapses are not occurring as frequently now as formerly. Since the first of the present year we have had but one case, that of Sarah B., who received her injection Feb. 12, and developed her neuro-retinitis March 26. Moreover, this is the only one in which the symptoms were less severe and the only one whose vision was restored to practically normal. May this not be the result of more energetic treatment with salvarsan?

While of course the number of cases that we have had in the Dispensary is too small to permit us to make any too broad or too positive statements in regard to the effects of arsenobenzol, yet I feel this way about it. If, as most authorities claim, these ocular lesions following 606 are simply the manifestations of syphilis, and if, as it is declared, arsenobenzol has such a remarkable beneficial effect in clearing up the symptoms of syphilis, then I believe that in all of these cases of ocular relapses the injection should be repeated, and that as soon as the symptoms appear. There is no organ in which irreparable damage to the delicate tissues can result more quickly from an inflammatory process than in the eye. Treatment after the damage has been done will not restore the destroyed nerve or other tissue. If the relapsing lesion affected the mucous membrane of the throat or the skin, one would not hesitate to give 606 any number of times it was deemed necessary to eradicate the disease. Then why not if the symptoms happen to affect the eye?

As regards the therapeutic effect of 606 in syphilitic disease of the eye, there is no unanimity of opinion as to the curative effect of the new product in ocular disease. In interstitial keratitis of inherited syphilis, for which mercury is well nigh useless, salvarsan has, on the whole, given no better results. A few men have reported good results, but the majority think the malady little influenced by it. The relief of the photophobia is generally attributed to it. This has been our experience at the Dispensary. In two of the cases, both boys, aged twelve and thirteen, respectively, one of whom received two injections at intervals of two months, the other four injections at intervals of two weeks, I think the course of the disease was shortened somewhat. In both the corneae were quite clear and glancing after three months' treatment. Usually it requires anywhere from four or six months' to one or two years' treatment. Most of the men who have reported favorable results have given the injection several times.

Iritis and iridocyclitis of secondary syphilis, usually respond well to the drug and much more quickly than to mercury. Improvement can frequently be found on the day after the injection. In four cases treated at the Dispensary, improvement was rapid, with apparent cure in about ten days, whereas under ordinary circumstances it requires three to six weeks for complete cure. The eye showed improvement within a few days after the injection. Such rapid improvement is to be expected in such a vascular tissue where the drug can come quickly into contact with the causative factor.

As far as the optic nerve is concerned when optic neuritis exists as a result of syphilitic inflammation, most authors maintain that the injection of 606 has a most rapid and beneficial effect. Shanz, Wechselman and Selligsohn have reported cases of optic neuritis in which arsenobenzol was used with most favorable results. In three cases of papillitis reported by Shanz, improvement was noticed on the same day as the injection. In two cases of optic neuritis treated by injection at the Dispensary the improvement was marked inside of a week. When simple primary atrophy of the nerve exists the consensus of opinion is that no benefit can result from 606. In fact, the atrophic process seems to be unfavorably influenced by the drug. This seems to be the sole contra-indication for 606 in specific diseases of the eye. Some writers also maintain that no benefit results from the use of 606 in ocular paralysis. This has not been our experience in one case seen at the Dispensary. The patient, a woman 49 years of age, with specific history of twenty years' duration, was referred to the eye room on June 20, 1913, with a ptosis of the right lid, which had started one week previous. Examination showed complete ptosis of right eye, paralysis of internal, superior and inferior recti muscles. She received 606 on July 16; six days later all paralyses were very much improved. Ptosis had entirely disappeared and movements of the eye were almost normal.

Summing up the effects of 606 on the eye, I should say that no case of injury to the healthy eye has been proven. The consensus of opinion is that it is innocuous to the healthy eye. A favorable result from the application of this drug is to be expected in syphilitic disease of the iris, the chorioid and retina, and the optic nerve, in paralysis of the ocular muscles, due to syphilis, and sometimes in interstitial keratitis. As far as we can judge in the short time salvarsan has been in use, it must be welcomed as an effective specific remedy in syphilis of the eye, which seems especially indicated in cases in which speedy aid is urgent. It is not a panacea for ocular syphilis which can entirely replace our usual specific preparations. It is especially indicated when a speedy action is desired, as in primary ocular affections, or in secondary or tertiary symptoms, if a rapid impairment of function is dreaded.

ASSOCIATION OF AMERICAN MEDICAL COLLEGES.—The twenty-fourth annual meeting of the Association of American Medical Colleges was held in Chicago on Feb. 25. Five topics of medical education were discussed at the morning session; and in the afternoon there was a symposium on clinical teaching, and an address by the president, Dr. E. P. Lyon, of Minnesota, on "The Principles of Curriculum Making."

THE EARLY DIAGNOSIS AND TREATMENT OF DEMENTIA PRECOX.

By Edward Mellus, M.D., West Newton, Mass.

Our insane hospitals are full to overflowing, and notwithstanding the fact that we are adding each year to their capacity, the yearly increase in the numbers requiring care is so great that the problem of housing our growing population of insane is a tremendous one.

There are many reasons for this great increase in numbers. One of the most important is that the general public has come to feel, in spite of frequently recurring sensational charges of brutality, that the hospitals for the insane can and do care for their inmates humanely. This has resulted in the commitment in recent years of very large numbers of cases of senile dementia, filling the infirmary wards with feeble bed patients who require a great deal of nursing, and severely taxing the capacity of the hospitals.

But these senile cases, many of whom are only technically insane, showing only the expected breakdown of advancing years, have a fairly short expectation of life, and are continually making room for other patients. There is another class of patients, however, who come under the care of our institutions at an early age, and as their form of mental disease tends toward becoming chronic, without any necessary impairment of their physical health, their accumulation fills our wards with hopeless mental wrecks. I refer to cases of dementia precox. It is a fact, which need not be discussed, that the earlier a disease is diagnosed, and given proper treatment, the better is the prognosis. In the case of mental diseases, this holds true, as well as in other abnormal conditions. Yet, as a rule, patients who are suffering from a mental breakdown are not seen by physicians who have had experience in that line of work, until the disease is so far advanced that treatment in a hospital for the insane is sought as a last resort. Men who make a specialty of mental diseases do not often see their patients until the mental symptoms are quite pronounced, and it thus becomes necessary that the general practitioner should recognize the incipient stages of insanity, if we wish to make a great advance in its treatment.

I have already referred to two forms of mental disease commonly seen in the insane hospitals. If to the cases of senile dementia and dementia precox, we add those of manic-depressive insanity and general paralysis of the insane, or dementia paralytica, we will find that we have given the diagnosis of a very large percentage of our insane patients.

In manic-depressive insanity the prognosis is good, almost without regard to treatment. Although the disease is essentially a recurrent one, the patient will generally recover from the present attack, and it is a question how much that attack can be shortened by treatment.

General paralysis is a mental and physical disease, the mental symptoms usually being marked delusions of grandeur, followed by extreme dementia and death. This disease is so generally preceded by syphilis that by many of the most noted psychiatrists it is claimed that syphilis is always present in the etiology. The prognosis is invariably bad, and so far as the patient and his family are concerned, the fact that the average duration before death is only about two years, is a consoling feature.

Senile dementia is too common an ending for those unfortunate enough to outlive their usefulness, to need description.

I have dismissed these three large groups of cases thus summarily for two reasons. They are well known, and are not apt to go long undiscovered. Then, too, early treatment makes very little difference in the result; they get well or they die. On the other hand, I feel that an early diagnosis of dementia precox is much more essential in the light of the ultimate prognosis as influenced by early treatment. The prognosis in this disease is usually considered poor. I remember, not long since, when one of our state hospitals was severely criticised for including in its statistics a recovery in a patient diagnosed as dementia precox. This is no longer the case, though there are still some who insist that if there is a recovery, the diagnosis of dementia precox must have been an error.

In many physical diseases, we are familiar with certain well known prodromal symptoms, whose appearance causes us to take immediate steps for the safety of the patient or those about him. In dementia precox we often learn, when it is too late, that the patient has, for a long time, shown symptoms that should have been interpreted as danger signals. Unfortunately these signs are not heeded, for they are displayed only before parents and relatives, who are too blind to see them.

There is probably no form of mental disease where heredity plays such a tremendous part in the etiology as in dementia precox. I do not mean that you should expect always to find a history of insanity in the parents, but rarely will a case be found without some mental or neurotic taint in the family. The parents are very often eccentric, to say the least, and it is not to be wondered at that their prejudiced eyes should see nothing abnormal in their children, until it is apparent to everyone else. If, then, the parents cannot be expected to discover the early signs of an oncoming dementia precox, it is very necessary that the only ones left who have a close intimate relationship to the child, the family physician and the teacher, should be thoroughly familiar with the symptoms.

Kraepelin states that at least 70% of dementia precox cases show hereditary factors in the etiology, but that only 17 or 18% is found in

direct ancestry. A careful analysis of histories, however, would lead us to place this latter estimate much higher. We often find in the history of the parents that the home surroundings were not comfortable, that one or both parents were unable to adapt themselves to commonsense relations, or that the father, for example, had not made a success of life. Many of these cases of marital incompatibility, and of the unambitious, unsuccessful drones, were very probably mild cases of dementia precox themselves, or the results of the same disease, with partial recovery.

When we consider that heredity is so important in the etiology (in fact Clouston insists that heredity is always present), we should be prepared to find that there is a distinct type of personality that seems predisposed to this form of mental disease. This is the case, and August Hoch has given this type a name which is very apt, the "shut-in personality." Jelliffe, in an article on pre-dementia precox, describes this so well, that I will quote a passage:—

"My own observations of patients whom I have known intimately since childhood have shown that the paranoid dement in particular has been rather abnormally brilliant, but with the lights turned inward rather than outward. They were extremely unpractical in the use of their hands, or in any adaptation to material ends. They were utterly unable to observe with accuracy anything physical or material, for their minds were constantly turned in upon their own meditations. They were all unready to adapt themselves to uncongenial environment. . . They were subject to fits of abstraction, when they would not hear or see what would attract a normal youth. They were usually irritable to their families, but most desirous of being thought either amiable or brilliant by strangers. They were abnormally sensitive and suspicious, and most were prone to discuss deep, unsolvable questions."

It can scarcely be claimed that all such children as have just been described are really partially developed cases of dementia precox, but there is very little doubt that in such children we have a very fertile field for the development of the disease. If physicians would bear in mind that such children, especially where there is a known hereditary taint in the family, are in danger, and would take steps to prevent further development, a tremendous amount of good could be done.

You may easily imagine from this that dementia precox is a disease of childhood, and though that is essentially true, many cases show the first symptoms much later. The fact that in a large percentage, however, the trouble first appears at or about the age of puberty or of adolescence, and in many other instances during pregnancy or the menopause, has led many psychiatrists to contend that it is in reality a product of auto-intoxication, probably caused by some internal secretion of the testicle or ovary. Considerable investigation is being done in this line, and more light may be shed on the etiology.

The onset of the typical symptoms of the disease is very gradual, and though cases of an abrupt onset are reported, it is very seldom that such are substantiated by careful investigation. Loss of ambition, indifference, sudden and unaccountable fits of temper, suspiciousness, and a desire to be left alone by former friends and companions,—all of these are typical symptoms of beginning dementia precox. Inability to concentrate the attention, lack of judgment and the habit of shifting from one line of work to another, are other symptoms. If there are delusions, though these are not usually among the early symptoms observed, they are apt to be especially noticeable because they are silly. I will not attempt to describe the later symptoms, such as peculiar mannerisms, negativism, mutism, stereotypy, cataleptic conditions, etc., for they only appear when the disease is so far advanced that, as a rule, the patient has already been committed to an insane hospital.

A short account of a patient formerly under my observation will give an illustration of a fairly typical case of dementia precox:—

In this case there was a very marked insane heredity. The father is strong physically, but admits that he is very nervous. The mother was a patient at McLean, twenty years ago, and is at present a woman of very poor judgment and very emotional. She has recently had a nervous breakdown and went for treatment to a private sanitarium. A sister of the mother is at McLean, where she has been for some years. Another sister has been at McLean. A third sister who is in the West, has broken down mentally. A brother was never in any institution but was admittedly unbalanced. The patient's maternal grandfather died of apoplexy and his maternal grandmother had melancholia and died of paralysis.

On the father's side, the history was nearly as bad. An aunt is now a patient at Worcester, while his grandfather committed suicide and his grandmother died of tuberculosis. There is probably even more hereditary taint in the family history, as even this much was only admitted after very close questioning.

The patient himself was delicate as a child and very nervous. He had a strong temper and a stubborn will. He did what he wished and would take advice from no one. He seldom played with other boys, but spent his time working with machinery and electrical appliances. He was fond of music and became very proficient instrumentally. He liked school also, and as he was bright in his studies, was encouraged in this line and went to college, where he graduated with honors. While at college he kept up his music and took work at the Conservatory of Music. He neglected his own comforts, was very irregular about his meals and often did not get sufficient sleep.

After leaving college, he tried several pursuits but never kept at one thing for any length of time. He tried life insurance work, was for a time in a banking office, dropped his work entirely and read German for a few months, formed an orchestra of which

he was the leader, and worked for a time with the men destroying gypsy moths. He enlisted in the navy as a musician but soon disappeared. He was later found working in a machine shop and was arrested as a deserter. He was discharged from the navy because of his mental condition and was committed.

In this case, I believe that much could have been done to prevent his breakdown if he could have been properly held back and not allowed to have his own way in everything. Of course, with a family with such a taint, it is impossible to expect that proper judgment would be used in bringing up such a precocious child, and perhaps the only possible prophylactic measure would have been the prevention of the marriage of two such neuropathic parents.

The fault has been found with most of the text-books on mental diseases, that they go into great detail concerning the etiology, pathology and symptomatology, but are very unsatisfactory in their recommendations for treatment. This is particularly true when the disease in question is dementia precox. White, at the head of the Government Hospital for the Insane, at Washington, whose "Outlines of Psychiatry" is used as a text-book in many of our schools, says, "These cases will, of necessity, have to spend most of their lives in a hospital. It is, therefore, desirable to educate them as early as possible in good habits. They should be encouraged to some form of education, preferably out of doors. Under the influence of hospital surroundings and farm life these cases may get on very comfortably and the dementing process be considerably retarded." This is all he has to say about treatment, with the exception of advising the correction of any functional abnormalities.

The text-books, however, are written as a rule by hospital men, and as they seldom see cases of dementia precox until they are fairly well advanced toward the hopeless later stages, it is not to be wondered at that their views are so pessimistic. If we are treating a case of yellow fever and do not begin treatment until the appearance of black vomit, about all we can do is to arrange for digging the grave.

Let me quote once more from White: "It is to be hoped that some day we shall have a sufficient understanding of character to be able to pick out those types liable to develop psychoses and to protect them from that class of stresses that they are least able to withstand. At present we can hardly be said to approximate to this. The neurotic child, however, can be recognized, and should be safeguarded, especially throughout school life and the period of puberty and adolescence. Some day, perhaps, competent advice will be sought by parents as to the best methods to be employed in the rearing of their children. Until then we are largely helpless in the matter of prevention."

Here is the point that I want especially to emphasize. The man in general practice is the one who can do this best. Those of us who are specializing in this work must keep in closer touch with the general practitioner and encourage him to discover these cases early and begin treatment before irreparable damage is done. These same men in general practice, commit patients to our insane hospitals, but how many of them ever visit the hospital to follow and watch the patients they send there? Perhaps they feel they would be intruders, but I am sure they would be welcomed at any of our hospitals.

Children, whose parents or family have a marked neurotic taint, especially if they show signs of precocious brilliancy, should be closely watched and kept from unnecessary stress. In school they should be held back, and not encouraged by ambitious teachers and admiring parents to outstrip their comrades. Instead, they should be compelled to keep out of doors and enter into games with other children. Bashful little "shut-ins" should be coaxed out of their shells and encouraged to make friends. Those who show especial aptitude for music or art, should not be allowed to spend too much time with these studies at the expense of other necessary, though more prosaic pursuits, for it must be remembered that there is a very thin partition between genius and mental trouble. The child's environment should be noticed. If, as is often the case, it is an only child, it is often well to advise a boarding school, for with all the well-known disadavantages, the close association with other children is better than being too much with "grown-ups."

One other way in which the general practitioner can do yeoman service, is by advising against marriage in every case where it is feared that some neurotic taint might be transmitted to future generations. We are not justified in saying "Marry if you wish, but don't have children." Many a marriage has been unhappy because of an unsatisfied yearning for children. Advice on this subject from the family physician is much more often followed now than formerly, largely owing to the campaign of education carried on by such organizations as the National Committee for Mental Hygiene.

While on the subject of treatment, I wish to make brief mention of the latest development in the treatment of mental diseases. Probably for the very reason that writers on insanity have so little to suggest in the way of treatment, they are apt to follow any new fad that offers hope. The latest fad is psychanalysis, and though it undoubtedly has much of good in it, especially in the treatment of hysteria and neurasthenia, I am much opposed to its use in cases of dementia precox. Without going into its sexual aspect, which repels many of us, it seems to me that dementia precox patients are all too introspective anyway, without any further encouragement. Personally, I have seen this treatment used on only one case of dementia precox, and the apparent results were very bad.

As I said early in this paper, the prognosis in dementia precox is considered bad. However,

recently, numerous recoveries have been reported. Many of these have been for private hospitals, as is to be expected, for they have the advantage of receiving patients early, before the family would be willing even to think of a state hospital. Many of these recoveries would probably show some deterioration on careful examination, but if they are able to return to their homes and lead useful lives, why are they not just as properly classed as recoveries as cases of manic-depressive insanity when the expected usually happens, one or many recurrences.

DIABETES AND SURGICAL OPERATIONS.

BY CHARLES GREENE CUMSTON, M.D.,

Privat-docent at the Faculty of Medicine; Fellow of the American College of Surgeons; Honorary Member of the Surgical Society of Belgium, etc., Geneva, Switzerland.

IT is at present an acquired fact, that diabetics may be submitted to operations of vast import with a successful outcome. To give a general idea as to what can be accomplished I will cite a few cases at random. Chavannaz has operated on five diabetics with one death. These cases were a laryngeal carcinoma, death eight days later; malignant disease of both ovaries, cure; castration for orchiepididymitis, cure; two amputations at the thigh, cure by first intention. Caralp (*Thesis*, Bordeaux, 1912) records one amputation of breast by Willy Meyer's method for an ulcerated carcinoma of breast, cure; three amputations at thigh for diabetic gangrene, all recovered; two hysterectomies for fibroid, both recovered; one palliative curettement for cancer of cervix uteri, cure; five trepanations for mastoiditis, with two deaths. The fatal cases were due, in one to old age, the patient being 76 years old; the other presented acetone in the urine. Richard operated on a buccal cancer successfully, Redard an epulis, Israel several cases of renal cancer and a suprapubic cystotomy, without any deaths. To these cases I may add six of my own, namely, one amputation at thigh for diabetic gangrene, death; one suprapubic prostatectomy, recovery; one strangulated hernia, and one amputation of the great toe and excision of two carbuncles, all successful.

Now, although diabetics are operable, the chances of success are naturally the greater when they have been first submitted to an antidiabetic diet in order to reduce as much as possible the glycosuria. This diet should be followed until the patellar reflex has returned, if it was found absent. The treatment should be very minute in all details, although it must be admitted that operation has been successful in instances in which time has not permitted a long period of diet and antidiabetic treatment. It goes without saying, that when the operation is not urgently indicated one should carefully prepare the patient, selecting either Bouchardat's or Cantani's regimen as being the most rigorous.

My cases were submitted to a diet of broiled meat, potato and gluten bread, with the administration of bicarbonate of soda and Vichy water. Antipyrine and lithium carbonate are also of value. The present-day diet generally employed seems to be roasted or broiled meats, purée of green vegetables and gluten bread. This regimen is advantageous, inasmuch as it diminishes the hyperglycemia. Alkalines particularly favor oxidation of organic substances and by their use the urine becomes less dense and less acid, the urea increases in amount, while the uric acid and albumin decrease, likewise the amount of sugar present.

The drugs resorted to as antidiabetic are more for the purpose of reducing the glycosuria than the hyperglycemia. Opium checks the thirst, diminishes the hunger and limits the glycosuria. It may be given in the form of Dover's powder, morphine or codeine combined with belladonna. In debilitated patients strychnine is useful, or when there is a diminution of sight or atony of the digestive functions. Valerian and arsenic act on the metabolism. The former drug has a favorable action on the polyuria and polydypsia, it also decreases the urea. Arsenic acts as a vascular tonic and influences metabolism, but its results are, on the whole, doubtful. In moderate doses, glycerine may counteract the loss of flesh. Ricord, long ago, prescribed iodine in sudden recurrence of diabetes, while the tincture of iodine, 5 to 20 drops at meals, has been given by Bérenger-Férand, and the syrup of the iodide of iron by Bouchardat.

Various acids have been prescribed, such as carbolic, nitric, salicylic and phosphoric, likewise, sodium salicylate, chloral, cocaine; astringents, like alum, tannin, etc.; oxidants, such as potassium chlorate or permanganate, inhalations of oxygen, etc. Antipyrine has given remarkable results, but as soon as it is stopped the sugar returns in the urine. The hydrochlorate and valerianate of quinine have given good results. Bar and Blum praise glutaric acid as a very active antiglucosuric remedy. But besides a proper diet, I believe that bicarbonate of sodium, the salts of lithium and antipyrine, represent the surest means of controlling the morbid process.

When once we have the diabetes under control, the analysis of the urine having shown a constant decrease in the amount of sugar from the effect of treatment, and having revealed no evidence of a serious lesion of the renal or hepatic glands, the reflexes being normal, what is the next step to be taken by the surgeon? I am firmly convinced that the diabetic diathesis plays no part in the complications arising after a surgical operation. It only acts by depressing the organism and facilitating infection, the

sugar present in the tissues being an excellent medium for the growth of bacteria. Then, too, experience has demonstrated that anesthesia and the operation *per se* are factors to be considered.

Years since, the great Claude Bernard showed that glycosuria occurred after the administration of chloroform from irritation of the terminal filaments of the pneumogastric, and all surgeons are aware that in normal subjects temporary glycosuria after chloroform is not uncommon. Chloroform undoubtedly disorganizes the hepatic and renal cells and reacts on the nervous system. Ether is not free from criticism, and the same may be said of ethyl chloride and somnoform. It is, in my opinion, safer to resort to local anesthesia when possible, but if general narcosis is required, it should be of as short duration as possible, the quantity of the anesthetic being reduced by a preliminary narcosis with somnoform or ethyl chloride.

The most absolute asepsis is required. It is not the sugar circulating in the blood wherein resides the danger, but the association of pathogenic bacteria with the sugar. Then, as diabetics are weak physically, it naturally follows that the loss of blood is to be avoided.

There are certain affections which are more or less dependent upon the diabetes, such as abscess and carbuncle. General pathology teaches us that the greater the acuteness and intensity of the infectious process, the more rapid and free shall be the surgical interference. Therefore, in diabetics particularly, large and free incisions are to be made in the abscesses, and in the case of carbuncle the lesion shall be freely excised. The same may be said of diabetic gangrene, which results from an excoriation or a small wound. Local treatment is useless and high amputation of the limb is essential if a successful outcome is to be obtained. Frequently after these major amputations the sugar will be found in lesser quantity than before the interference. Let it also be said that a temporary glycosuria has been met with in cases of extensive abscess or carbuncle which has led the surgeon to suspect diabetes, but free drainage of the septic focus in the one, and excision in the other, has led to the disappearance of the sugar in the urine.

To sum up the question, I would say that in all cases of diabetes requiring operation, when the latter is not urgent for the saving of life, the patient should first be put upon a strict diet and treatment with drugs. When the glycosuria is sufficiently under control the operation may then be proceeded with. The reflexes should be nearly normal for a good prognosis, although this is not absolutely necessary. The urine should not contain either acetone or B. oxybutyric acid. The presence of urobilin or albumin should be a warning against interference. The quantity of urea secreted should be nearly normal. The length of time required for the operation and the quantity of the anesthetic given should be reduced to a miniumm, likewise the loss of blood.

Clinical Department.

THE SIGNIFICANCE OF EARACHE.

By Irving Sobotky, M.D., Boston.

"Doctor, I have a terrible pain in my ear." This statement, so often heard and so often made light of by the physician, should be the same danger signal to him as severe pain in the right iliac fossa and should be watched just as carefully as a case of acute appendicitis.

Too often the complaisant practitioner does not recognize the seriousness of earache and believes his duty done when he orders hot sweet oil to be dropped into the ear.

Now, what must the physician consider from the one symptom of earache? He must think of acute otitis media, acute catarrhal otitis media, furuncle of the auditory canal with or without diffuse inflammation, otalgia dentalis (earache due to decayed teeth). Neuralgia, affections of the maxillary antrum and tuberculous laryngitis cause referred pain in the ear, but are beyond the scope of this paper and are only mentioned as possible causes of earache in the absence of any other etiological factor.

By far the most common and the most dangerous cause of earache is an acute otitis media. Dangerous, because it can rapidly develop into a mastoiditis and a meningitis, especially in children. That is the reason why it must be recognized and treated at once; why every effort must be made to detect the tenderness on pressure, that is present when the mastoid antrum becomes involved and why the case must be referred to a competent otologist the instant there is the slightest evidence of the existence of this mastoid tenderness. Only an otologist is capable of treating a mastoiditis.

In order to recognize the condition causing the pain, the physician must be familiar with the normal appearance of the tympanum and thus be able to compare it, intelligently, with the picture presented by an acute otitis media. The text books on otology, give clear descriptions and pictures of the normal appearance of the tympanum. This study should be supplemented by the examination of normal ear drums and the identification of the landmarks.

Before examining the patient, however, these three questions can be asked. How long have you had the pain? Did the pain keep you from sleeping? Is there any discharge from the ear? The first question gives the examiner some idea of the duration of the infection. The second is a measure of the severity or intensity and the third raises the question of sufficient drainage.

A satisfactory examination of the ear cannot be made unless the ear is thoroughly wiped free of any cerumen or secretion, but it must be

borne in mind that this cleansing will produce some hyperemia, both of the tympanum and of the auditory canal.

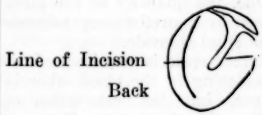
The picture presented by the affected tympanum should now be compared with the normal. If the tympanum is of a scarlet red shade and bulges into the auditory canal and the long process of the malleus is invisible, a diagnosis of acute otitis media (suppurative) can be made. However it is not always easy to make the differential diagnosis between a suppurative and a catarrhal otitis media, especially in the early stages. As a rule the pain is much more severe and the temperature from one to two degrees higher in an acute suppurative otitis media.

As in abscess formation in other parts of the body, complete drainage of the middle ear cavity must be immediately established by means of a free, curved incision of the tympanum, or in other words, a paracentesis must be done even if the ear has commenced to drain.

If the tympanum is a yellowish red color with wavy, hair-like lines running across (exudate lines) with perhaps a few small air bubbles in the lower posterior quadrant and the pain not especially severe nor the temperature above 100 F a diagnosis of acute catarrhal otitis media must be made. In this condition the malleus is visible but the long process shows hyperemia sometimes of a high degree. At the onset of a severe catarrhal condition the appearance of the drum is very similar to the acute suppurative middle ear.

The treatment is the same as the suppurative type, namely, a paracentesis but in contrast, if there is no free drainage after the paractentesis has been done, the middle ear should be gently inflated, per Eustachian tube, and the secretion thus forced through the incision in long, tenacious, mucous strings.

As a proper paracentesis is the essential treatment, the technique will be described.



It is usually not necessary to use a general anesthetic; a local application of equal parts of menthol, cocaine and carbolic acid mixture, will give a high degree of insensibility to pain if applied to the tympanum, for five minutes, in the form of a soaked cotton tampon.

A free incision is best obtained by the use of a sharp paracentesis knife, shaped like a scalpel or curved bistoury. The arrow head shaped paracentesis knife is unsuitable.

Previous to the operation the canal should be mopped out with cotton moistened with alcohol. The instruments should be sterilized with alcohol or by boiling, and the hands should be carefully sterilized.

After sterilizing the knife, the ear speculum, and the hands, the index finger of the left hand should be placed in the convolution of the auricle, just above the external meatus and traction exerted in an oblique direction, upwards and backwards in adults, and downwards and slightly backwards in young children. This straightens the canal. With the patient's head firmly held, the knife should be introduced along the posterior part of the floor of the canal, with the cutting edge directed upwards. With an *absolutely clear* view of the tympanum the curved incision should be made in the posterior quadrant by puncturing the tympanum almost at the lower border of its attachment and incising from below, upwards. (See cut.)

Care must be taken not to insert the knife so deeply as to wound the promontory mucous membrane. After wiping out the discharge and the blood a cotton wick should be placed in the canal and instructions should be given to syringe the ear every two hours with a pint of hot boiled water, the ear syringe to be boiled at each syringing.

The patient should be seen every day until the discharge has ceased and every effort should be made to encourage free drainage as the acute symptoms may return should there be any obstruction to the flow of pus. Should these symptoms recur it is well to repeat the paracentesis.

The great danger of mastoiditis developing from an acute otitis media should compel the physician to examine very carefully the mastoid region at each visit. The neglect of the early mastoid symptoms may result in intracranial infection or in the necrosis of the anterior wall of the mastoid antrum and of the tip of the mastoid process, the abscess here showing itself as a large post auricular swelling with sometimes a burrowing of pus along the neck muscles.

As it is very necessary to differentiate between mastoiditis, and an inflammation of the auditory canal, the symptoms of both will be given:—The mastoiditis symptoms are chiefly those of pressure from the secretion in the mastoid cells. Pain, swelling, some redness and marked tenderness on finger pressure over the mastoid process together with a high temperature and constitutional symptoms are the distinguishing features of mastoid involvement. On examination with the ear speculum, a bulging may be seen in the posterior and superior wall of the canal, although this is by no means always present. Inflammation of the canal, with or without furuncle, causes great pain in the region of the ear, aggravated by moving the auricle up and down and by chewing. The diffuse inflammation may simulate the redness and bulging of the posterior superior wall of the canal in mastoiditis but differs, materially, in situation; the mastoid symptom being posterior and in the bony part of the canal, while the canal inflammation produces swelling in the in-

ferior wall of the anterior cartilaginous portion of the canal. The temperature is much lower than in mastoiditis and constitutional symptoms are lacking or very slight.

In all otitis media cases the throat and nasopharynx should be examined for enlarged tonsils and adenoid. The relationship of adenoid to frequent attacks of otitis media has been conclusively proven, hence it is the duty of the physician to *completely remove* the adenoid and enlarged tonsils after the acute symptoms have subsided. When removing the adenoid it must be the aim of the operator to remove all of the adenoid tissue, as a large central adenoid may not cause anywhere near the trouble that bits of adenoid tissue can produce in the fossa of Rosenmüller and around the Eustachian orifice.

Furuncle of the canal is a frequent cause of earache, but the pain is not as deep seated as in otitis media although it is usually more exquisite. Furuncle can readily be diagnosed as it is easy to see and moving of the auricle causes severe pain. The characteristic red swelling, about the size of a pea, extremely tender to probe touch and situated at or near the external meatus is in decided contrast to the findings in an otitis media.

The treatment of furuncle of the auditory canal consists of a free incision, under local anesthesia, the application of dry heat, and tampons of 10% ichthyol and glycerine or 3% carbolic and glycerine or 5% aluminum acetate solutions, renewed every three hours.

Impacted cerumen may cause pain in the ear but it is not severe. The presence of cerumen is easily determined and the treatment self evident.

If the ear has been carefully examined and no cause discovered for the pain, the teeth should receive the examiner's attention. Pain due to bad teeth is often referred to the ear and the prompt dental treatment of such a case will eliminate the earache.

In the absence of any of the above named conditions, the patient should be referred to a neurologist for an opinion as to the likelihood of neuralgia.

If the underlying cause is a tuberculous laryngitis or empyema of the maxillary antrum, the symptom complex will be sufficient to determine the diagnosis.

It often happens that patients complain of repeated attacks of earache either with or without suppuration. This is due, in the vast majority of cases, either to the naso-pharyngeal secretions being forced into the middle ear through the Eustachian tube, or by the blocking of the drainage by adenoid tissue at the Eustachian orifice. Hence every patient with such a history must be forbidden the use of nasal irrigations and must be warned against blowing the nose violently and thus forcing secretions into the middle ear.

If any adenoid tissue is present it is, of course, essential to remove it, as stated above.

SUMMARY.

This paper is intended as a plea to the practioner to treat earache with the respect it certainly deserves and as an aid to him for the recognition of the conditions causing the symptom.

Therefore these points are to be emphasized:

1. The cause of the earache must be determined.
2. Treatment must be prompt.
3. The patient must be closely watched for complications (mastoiditis).
4. If complications develop, despite careful treatment, the patient must be immediately referred to an otologist.
5. In repeated attacks of earache, nasal irrigations and violent blowing of the nose must be prohibited.
6. Enlarged tonsils and all adenoid tissue must be removed.

Reports of Societies.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

THIRTIETH ANNUAL MEETING HELD AT WASHINGTON, D.C., MAY 6, 7, 8, 1913.

The meeting was called to order by the President, DR. CHARLES L. MINOR, Asheville, N. C.

He said that this Association was the first society in the United States to pay special attention to tuberculosis. Valuable papers on climatic treatment, careful studies on the use of tuberculin, pioneer work on nomenclature and classification, important papers on early diagnosis and on pneumothorax, and many others which had a strong influence on the development of an interest in tuberculosis in this country can be found in the 28 volumes of Transactions. A glance at the list of officers and directors of the National Association for the Study and Prevention of Tuberculosis shows that the members of the Climatological Association have been active and prominent in it from the start, and that the latter is in justice the parent of the national society. The Association has made a study of mineral springs and climatic resorts. Dr. Minor outlined his plans for widening the scope of the Association.

DR. JAMES DUDLEY MORGAN, of Washington, presented a paper on "The Effect of Climatic Changes on Rheumatism and Neuritis." Rheumatism is a disease of temperate climates; it is not always most common in winter; it is most common in adolescence and manhood, when the powers of resistance are greatest, and in moderately low temperature accompanied by moisture. Soil and climate *per se* have little to do with rheumatism, but may lessen the resistance and render the system more open to attack. Bad ventilation favors the occurrence of rheumatism. Rheumatism, neuralgia and gout are made worse by the approaching storm. The case of Captain Catlin, described by Dr. Weir Mitchell in his article on the "Relation of Pain to Weather,"

published in 1877, was referred to. Dr. J. M. Roddy's article on "Weather Forecasts and Health," 1898, was quoted.

DR. HENRY SEWALL, of Denver, read a paper on "Auscultatory Determination of Early Pathological Changes in the Lungs." Dr. Sewall said that through auscultation of the voice and whisper we have unrivalled means for the detection of minute tissue changes throughout the pulmonary region; with these are included vocal fremitus and percussion resonance. The more marked tactile fremitus and vocal resonance, distinguishing the right from the left apex of the normal lungs, depends on the immediate contiguity of the former structure, with the resounding trachea, whose vibrations are thus transmitted transversely through the pulmonary tissue. Any infiltration of this tissue which improves its conducting or resonating properties must amplify and extend the sounds heard in auscultation. It is necessary to analyze the sounds into those vibrations due to resonance of the viscera and those of the chest wall. The latter vibrations can be damped by pressure of an appropriate form of stethoscope.

Vibrations transmitting the whisper are confined almost wholly to the viscera. Modification of the voice sounds by which their quality becomes more amphoric and their duration prolonged into an echo are the striking characters which, when accentuated by stethoscopic pressure, indicate pathological changes in the viscera. This method of examination reveals the intensity and distribution of morbid changes within the lungs, even when these changes are too slight to appeal to the senses through any other method.

DR. J. N. HALL, Denver: For nearly twenty years Dr. Sewall and I have had opposite sides of the same ward of the City Hospital, and I have seen the cases as they came in. I wish to testify to the striking work that he has done. I have seen him diagnose cases which were positively unique.

DR. W. H. SWAN, Colorado Springs: Dr. Sewall speaks of the value of the x-ray in showing the early stages of tuberculosis. I think we sometimes overlook very marked signs by ordinary examination when the x-ray shows them very distinctly. I recall now a case where several experts failed to recognize a well-marked and large cavity, but the x-ray showed a very distinct cavity, with definite outline and thickened wall. Even after it was demonstrated by the x-ray there were absolutely no physical signs to show it. This must lead us to be very cautious as to many of our physical findings.

DR. WILLIAM LEROY DUNN, Asheville, N. C.: I would like to know what particular formula the doctor has found especially adapted in this whisper voice in bringing out the best evidence.

DR. SEWALL: I direct the patient to repeat the words, "one-two-three" and note the prolongation of the sound from one syllable to the other, as well as the change in quality. If what I have said is true there is rarely need for any tuberculosis except in certain particular instances, to reach the open stage. My thesis is that the procedures of physical diagnosis within our reach are capable in the vast majority of cases of disclosing the presence of glandular and pulmonary tuberculosis in a stage so early that not only is the patient still non-infective, but is capable of responding to the curative measures of hygienic living.

DR. P. M. CARRINGTON, of the U. S. Public Health Service, read a paper on "The Climate of San Diego, California, with Relation to Renal Diseases." The author had recovered from a tubercular infection in New Mexico, and afterwards derived great benefit from a two years' residence in San Diego, where he was sent to recuperate from an attack of nephritis. The rainfall of San Diego is given as ten inches, occurring from October or November until March. The relative humidity ranges from 67% in December to 80% in July, with a mean annual of 75%. Occasionally temperatures of 100° F. have been recorded, and as low as 32° F. The equability of the climate is marked. The climatology of nephritis was discussed with special reference to the San Diego region. Cases were cited to show the benefits derived in this class of cases. It is a climate which necessitates no seasonal change of clothing, and suitable fruits and vegetables are grown all the year, making proper diet obtainable.

DISCUSSION.

DR. POTTENGER: We know there is a very great difference in the climatic conditions of places comparatively close together, because Los Angeles has one climate, Santa Barbara has a still different one, San Francisco still another. San Diego is particularly suited to this type of disease, having a very equable climate, free from rapid changes. At Monrovia, one hundred miles away, our daily variation is thirty degrees. If you will take the temperature at 7o'clock in the morning and add 30 degrees you will have the maximum temperature for that day.

DR. A. C. GETCHELL, Worcester: Many of the patients that I have to do with from time to time owe their troubles very largely to the effect of the climate in which they are living, and I hope that the men who live in these better climates will continue to impress upon us their importance in the treatment of pulmonary tuberculosis. It is true that it is impossible for large classes of patients to take advantage of the better climates. There is a growing tendency toward treatment of disease by hygiene and diet, and other matters which pertain to biology of the system. I think that the quality of atmosphere lived in and breathed is an exceedingly important matter in the treatment of disease, and the value of climate cannot be too persistently impressed upon us.

DR. CASSELBERRY: A brief sojourn at San Diego some years ago tends to confirm its climatic advantages as described by Dr. Carrington. There is not only equability of temperature, but the general quietude is conductive to equanimity of mind, with a disposition to get out into the sunshine, and but little disposition to do anything else.

DR. GEORGE W. NORRIS, of Philadelphia showed a series of lantern slides made from frozen sections of the cadaver, illustrating various anatomical relations of importance in thoracic diagnosis, such as: The relative distance of the lungs and heart from various points on the thoracic wall. (2) The causes for the physiologic differences in tactile, auscultatory and percutory findings on the two sides of the chest. (3) The position of the heart and lungs in cases of pleural and pericardial effusion. (4) The location of early and late tuberculosis lesions of the lungs. (5) The location of the cardiac valves in relation to each other and to the anterior chest wall.

Dr. Philip King Brown, of San Francisco, showed lantern slides illustrating the frequency and extent of peribronchial lymph-gland tuberculosis in cases with some constitutional symptoms without marked physical signs. The general tendency of infections from this source to extend upward to the apices, the plates showing the various stages of this extension. In general, the contribution of x-ray plates of the chest aids in the diagnosis of tuberculosis of the lungs.

Dr. J. C. Wilson, Philadelphia, read a paper on

BLOOD-SPITTING IN HEART DISEASE.

The syndrome hemoptysis occurring in cardiac cases is better studied in office work than in any other clinical relation. Its incidence is much more frequent than the literature would indicate. It is often overlooked in history-taking. Brief statistical studies: the clinical variations; the association with pulmonary lesions; difficulties in diagnosis; immediate and remote prognosis. Remarks upon treatment.

DISCUSSION.

Dr. J. M. Anders, Philadelphia, Pa.: I wish to emphasize the difficulty that I have met with in a few cases in differentiating aortic insufficiency associated with hemorrhage of the lungs from pulmonary tuberculosis. It is true that cases of aortic insufficiency associated with pulmonary hemorrhage form but a small percentage of the total. On account of certain symptoms, such as flushes and night sweats leading to exhaustion and blood spitting, all of which may arise in aortic regurgitation, this disease may bear a close resemblance to pulmonary tuberculosis. I agree with Dr. Wilson that the incidence of blood-spitting in cardiac diseases is greater than has been supposed. In the treatment, also, I fully agree that no special form of medication should be instituted, except in the very few instances where there is great exhaustion.

Dr. DeLancey Rochester, Buffalo, N. Y.: I do not think that we can always positively say that hemoptysis is due to heart disease alone without further inspection of the lung. I call to mind one case, exceedingly instructive, of a young lad with rheumatism, with an endocarditis, mitral stenosis and aortic insufficiency combined,—a combination which I rarely have seen. He came in spitting blood, and no tubercle bacilli were found in his sputum. He improved decidedly, and finally got up and was moving about the ward. He was suddenly taken with severe pain and hemorrhages, and he had all the signs of a pulmonary infarction. Tubercle bacilli appeared in his sputum. There was a case which would undoubtedly have gone without appreciation of involvement of the lung, except that he was under observation. The boy finally died of tuberculosis. Unfortunately, an autopsy was not allowed. Within the last two years there has been brought forward in Buffalo through the studies of Dr. Bush and Dr. Clowes, Dr. Bush being the professor of physiology, and Dr. Clowes assistant in the New York State Cancer Laboratory, a means of treatment of hemorrhage which has proved very successful in various cases. This is the production of a serum from which the antitrombine, which is normally in the blood, is removed by their method of procedure. I will not go into detail because a paper will be published in the *New York State Medical Journal* in regard to this matter. About 15 c.c. of the solution is made, and is injected subcutaneously, or in some cases intravenously, I think, which has as good results in one way or the other. These injections stop hemorrhage in many cases. In 5 cases, 3 of pulmonary tuberculosis and 2 of hemorrhages of the stomach, the results have been remarkable, the hemorrhage stopping within a few hours after the injection of the serum, and not recurring. Sometimes a number of injections are necessary, but I understand that this material will be put upon the market soon from one of the large manufacturing houses. Of course all hemorrhages cannot be stopped with a serum, but I think it is well worth considering.

Dr. J. H. Elliott, Toronto, Canada: I would like to relate one case, a woman about 36 years old, who has had recurring hemorrhage for some 15 or 16 years; they were supposed to be due to pulmonary tuberculosis. No tubercle bacilli had ever been found, but when I first examined her I found a fibrous condition of the right apex. The signs were slight, however. During the first two hemorrhages I could find no physical signs in the lungs. On the third occasion I was rather surprised to find the signs in the left apex, opposite to that which I had diagnosed formerly as tuberculous. At this time there was present, which I had not found before, a murmur of mitral regurgitation. The heart was somewhat enlarged; I had an x-ray made of the chest, and with the fluoroscope there was a pulsating tumor on the descending arch of the aorta, the side on which the physical signs of hemorrhage had appeared.

Dr. J. C. Wilson, Philadelphia: The importance of blood-spitting in heart disease depends on two facts. First, that in the great majority of cases the blood lost is very small and the hemorrhage occurs at long intervals. Its symptomatic value may for this reason be wholly overlooked. Second, that hemoptysis, to many practitioners, suggests disease of the lungs rather than disease of the heart. Hence uncertainties, even errors, in diagnosis. The difficulties in diagnosis are increased by the occasional occurrence of copious blood-spitting in heart disease and in associated cardiac disease and pulmonary tuberculosis. The necessity of a correct diagnosis in any given case arises from the facts that blood spitting in heart disease tends to relieve congestion and is often followed by relief of symptoms and does not really call for energetic treatment; whereas the blood-spitting of lung disease usually demands active therapeutic measures, and is liable to be followed by fever, broncho-pneumonia and an extension of the original process.

Dr. Joseph H. Pratt, of Boston, made a communication on "The Action of Carbon Dioxide Baths on Blood Pressure, with a description of a new functional Test of Cardiac Efficiency." The author has been making these observations on carbon dioxide baths for eight or nine years. Shortly after these baths were employed in heart disease the claim was made that the pressure was raised because it was thought desirable in these cases to raise it; later the announcement was made that the action was to reduce blood pressure. Gottfried Müller, in careful studies of the action of these baths in healthy subjects, concluded that their chief action on the blood pressure was dependent on the temperature of the water. Dr. Pratt used a bath of

40 gallons of water at 90° F. for ten minutes, containing 1000 c.c. strong hydrochloric acid and 1000 gms. of sodium bicarbonate. He does not use calcium chloride or sodium chloride. In a case of moderate cardiac inefficiency there will generally be a silght elevation of the blood pressure. He found also that in cases of marked cardiac inefficiency there was a fall of pressure at that temperature. Dr. Pratt advanced the opinion that the response of the blood pressure in a given case of heart incompetency, when treated by carbon dioxide baths of the strength noted, is an index of the degree of the incompetence, and in case of a fall this plan of treatment would be counterindicated.

DR. JUDSON DALAND of Philadelphia read a paper entitled "Clinical Observations on Blood-Pressure." Dr. Daland prefers the mercurial instrument as being more accurate. Diastolic pressure observations are often omitted whereby valuable information obtained from a study of the low and mean pressure is lost. Repeated examinations were advised. The whole subject was analyzed. Time of day, occupation, position, temperament and circumstances connected with a visit to the physician's office modify the record. Extraordinary variations, all tending to hypertension, are observed in the neuropathic. Driving an automobile for two hours through crowded streets caused an increase of 30 mm. in the systolic blood-pressure and 15 mm. in the diastolic. Neurotic women, experiencing fright when having pressure measured, have a marked rise. Hypertension due to uremic states is usually uninfluenced by most drugs. In a case of Addison's disease with great destruction of the adrenals, the systolic pressure was 90 mm., and the diastolic pressure was 70 mm.

(To be continued.)

Book Reviews.

Practical Prescribing, with Clinical Notes. By ARTHUR H. PRICHARD, M.R.C.S., L.R.C.P., R.N. London: Henry Frowde, and Hodder and Stoughton 1913.

This volume in the Oxford Medical Publications series is essentially a case-history book in internal medicine,—the first of its type in England. The author's aim was to supply information of service to students and practitioners wishing to obtain practical knowledge of prescribing. The common medical diseases are grouped under convenient pathologic or regional headings, and each is illustrated by one or more selected, epitomized cases, with treatment, note, and comment. Though somewhat different in mode of presentation, the method is essentially that familiar in the highly successful American case text-books. The value and vitality of this method of instruction are now so well recognized in this country as to require no further comment. The present volume is evidence of the beginning development of a similar advance in British medical teaching.

The Practitioner's Practical Prescriber. By D. M. MACDONALD, M.D. London: Henry Frowde, and Hodder and Stoughton. 1913.

This small volume in the Oxford Medical Publications series is intended as a pocket formulary and epitome of symptomatic treatment. Portions of it have already been published discretely in the *Clinical Journal*, the *Practitioner*, the *Hospital*, and the *British Medical Journal*. The first part, comprising about three-fourths of the book, is an alphabetic syllabus of the therapeusis of common diseases from abortion to whooping-cough. The second part consists of juvenile and adult posologic tables; the third gives practical directions and points in prescribing; the fourth enumerates the common incompatibles; the fifth consists of "therapeutic brevities"; the sixth describes the treatment of emergencies in everyday practise; and the remaining sections deal with diet tables, gavage, recipes, duration of pregnancy, and other miscellaneous information. On general principles, one does not approve such rule-of-thumb reference books and compendia, but the present manual seems in the main accurate and as little objectionable as any of its class.

The Deaths of the Kings of England. By JAMES RAE, M.A., M.D. London: Sherratt and Hughes. 1913.

From time to time during recent years there have appeared in the *British Medical Journal* interesting articles on the death-beds of several British monarchs. Further study on this subject is, however, now made superfluous by this admirable and absorbing work of Dr. Rae. He has collected from records and historic manuscripts the authentic original data in the case of each king, or ruler, and of his consort, presenting a complete case-history series, with diagnostic discussion, from William First to Fourth. Moreover, in his introduction, he has analyzed this series of cases, classifying the various causes of death, as in vital statistics. Interestingly enough, in spite of the almost continuous relationship between the patients, there is a striking absence of familial or hereditary disease. Chronologically the kings fall roughly into groups, in which the cause of death corresponds approximately with the conditions of life. The early, campaigning kings, died of trauma or dysentery, those of medieval times by infection, those of recent times of pulmonary, cardio-renal, or circulatory disease.

The volume is not only an excellent piece of medico-historical research, but might to advantage even be employed as a text-book for case-teaching in clinical diagnosis. The author deserves the greatest praise for the scholarly and scientific accuracy and literary merit of this unique monograph.

THE BOSTON

Medical and Surgical Journal

THURSDAY, FEBRUARY 26, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

TUBERCULOSIS FOLLOWING TYPHOID FEVER.

SOME time ago Lieutenant-Colonel Charles F. Woodruff of the Medical Corps, U. S. Army, now retired, became impressed with the idea that tuberculosis was extremely apt to follow typhoid. During the past two years he has been engaged in extended and painstaking researches in this country and in Europe, with a view to ascertaining whether this were actually the fact or not, and in an elaborate paper read at the January meeting of the Medical Association of the Greater City of New York he made the distinct claim that there is a definite relation between the two diseases. Some preliminary comment on this paper was made in the issue of the JOURNAL for Feb. 12 (p. 259).

It is not strange, he thinks, that medical literature should be so devoid of studies regarding this matter when we consider that the long interval which may elapse between the beginning of tuberculous activity and the onset of symptoms generally prevents the discovery of the activating cause. Consumptives appear to have had more typhoid than the rest of the population, though there is no way of determining this point accurately. Statistics which were quoted indicate, however, that such is probably the case, and there are other facts which, taken together, are believed to show a relationship between typhoid and tuberculosis, though each by itself is of little value. Thus, the mortality curve of tuberculosis, which rises rapidly from childhood, reaches its maximum before thirty and declines after thirty-four, while the maximum in the curve of typhoid is reached at fifteen and declines after twenty-five. The curve of tuberculosis seems to follow that of typhoid after an interval of about nine years, and the average length after tuberculosis is said to be seven years. This might mean, therefore, that the typhoid, mostly contracted before twenty-five or thirty, has been partly responsible for raising the maximum mortality from tuberculosis nine years later. Again, it is significant of the relation of typhoid to tuberculosis that males predominate in the deaths from both causes. Furthermore, where typhoid fever is prevalent there should be more tuberculosis than in places free from typhoid, and variations in the typhoid death-rate should be followed by similar variations in the tuberculosis deaths there. It is also evident that in a place where tuberculosis is quite common, typhoid should have more effect in increasing the death-rate from tuberculosis than in places having little tuberculosis.

These propositions, Colonel Woodruff believes, would seem to be proved by a series of charts which he found in the Office International d'Hygiene Publique in Paris, in which it is worthy of note that the two curves show more or less parallelism throughout the civilized world. On the charts are given the curves for other infections,—smallpox, diphtheria, scarlet fever, and plague; but these came in epidemics, and presented irregularities having no apparent relation to the two endemic diseases. Unfortunately, neither measles nor whooping-cough, which, together with typhoid, he regards as the diseases most frequently followed by pulmonary tuberculosis, was considered of sufficient importance to record, and there is no means of determining how far they were responsible for irregularities in the curves. The curves indicate, in general, that for every reduction of five deaths by typhoid there are more than three lives saved from death by tuberculosis in the time covered by the charts. Karl Pearson, the eminent statistician, warns, indeed, against drawing conclusions from parallel curves, as it not infrequently happens that there are two independent causes at work, one for each set of facts, and wholly unrelated; but in view of the evidence that typhoid is frequently followed by tuberculosis, Colonel Woodruff thinks there can be no reasonable doubt that the reduction of

typhoid is responsible for a good share of the modern reduction of tuberculosis.

He stated that in the United States Army the dependence of tuberculosis upon typhoid was seen after 1890, when, as in civil life, bacterial diagnosis became more common; but after antityphoid vaccine was widely used, tuberculosis ceased to decline with the typhoid. Major F. F. Russell of the Army Medical Corps, who was largely instrumental in having antityphoid vaccination introduced into the army, was one of those who participated in the discussion of the paper, and he took issue very decidedly with its author in regard to the latter statement. If, he said, the contention were true that such vaccination activates tuberculosis, there should have been some increase in the amount of tuberculosis in the army; whereas the records published in the annual reports of the Surgeon General distinctly showed that for the past five years, during three of which antityphoid vaccination had been compulsory, there had been a steady decline in the disease.

REORGANIZATION OF THE MASSACHUSETTS STATE BOARD OF HEALTH.

THE recent report by a surgeon of the United States Public Health Service upon the public health administration in Maryland is of particular interest at this time in Massachusetts since the question of the reorganization of the State Board of Health has come up. Dr. Fox made a careful study of the state department of health and under agencies, having sanitary functions, in the state of Maryland. His study continued during the last six months of 1913. Some of the conclusions are particularly timely.

"From this investigation it is seen that the state board of health has been merged into a department in which, however, it retains the executive control and quasi-legislative powers. Since the board does not sit constantly, however, in the interim of meetings the duties arising must be performed by the executive officer of the department. At least theoretically, therefore, the responsibility and the power of initiation to meet emergency does not appear to rest squarely enough on the administrative official whose duty it is to handle the executive work."

"Furthermore, by reason of the method of appointments on the state board of health it would be possible at any time for its personnel to be so changed for political reasons as to include members without the necessary knowledge of public health needs. While the present board is composed mainly of men of eminence in public health matters, who support the secretary in his actions, it might at times become political at the will of the governor of the state."

"Generally speaking, state boards of health by reason of their organization and slow-moving methods are not in position to exercise all the functions which should be required of a department of health. The state department of health should be able to act quickly and efficiently, and in our opinion this can best be accomplished when it is presided over by an all time health official who has as his subordinates a sufficient number of capable bureau chiefs and a board or council composed of public officials, business and professional men, to act in an advisory capacity only. This officer should have the power of initiation and he should have as a part of his department an adequate county or district health organization which should be subject to the control of the state department and work under it for the prevention of disease and the improvement of the public health."

"It would appear to be the modern tendency to place organizations such as departments of health under the control of one head, as instanced in the states of New York and Pennsylvania, and in the Philippine Islands."

The argument seems to us to be sound. We believe that the same conditions and the same reasons which induced the special public health commission of the state of New York to recommend, and the New York legislature of 1913 to vote to change a state board of health into a system of a single highly paid commissioner of health with an advisory board hold equally well in Massachusetts.

There are a number of bills before the present legislature with the view of reorganizing the state board of health. Practically all of them call for a paid board of several members. According to the Public Health Bulletin, No. 54, of the United States Public Health Service, only one state has a paid board of health. The other states have either unpaid boards or a single commissioner. It seems to us that the tendency of the times and the weight of authority is entirely in favor of the single commissioner of health with an advisory board. Experience has shown that men of large calibre and of great experience in public health will give freely of their time

to the state in an advisory capacity. The entire time and services of such men cannot be secured by the state on paid boards. If the state board of health is to be reorganized, and on the whole reorganization seems desirable, we disapprove of the paid board of health and heartily endorse the system of a single highly paid commissioner of health in authority, with an advisory unpaid board.

UNIFORM CHILD LABOR BILL.

THE legislature of 1913 made an important step in public health by passing in its essential form, the uniform child labor bill. The uniform child labor bill had been carefully considered for a number of years and was adopted by the Commission on Uniform Laws only after prolonged careful study. The essential part of the bill was the reduction in the hours of work for children under sixteen, from ten hours a day to eight hours a day. In other words, it made compulsory in all the occupations throughout this state, the standard hours of work that are accepted by the state and by most municipalities when they employ labor. From a public health point of view, this was a sane step towards a better and healthier class of workers. It is generally agreed that to attach a child of fourteen to a machine for long hours each day makes that child prematurely old. The reduction of a working day to eight hours is little enough, but it gives a child from fourteen to sixteen some opportunity for out-of-door exercise and recreation, and counteracts to some extent the serious effects of fatigue upon the nervous system.

As might be expected a number of bills have been introduced into the Massachusetts legislature this year either to repeal or to modify this law so that children under sixteen can again be worked ten hours a day. In the daily press there have been featured some irresponsible statements that the child labor law of 1913 has thrown children out of work and has allowed them to roam the streets in idleness.

Careful investigation of the facts has shown, in the first place, that few children have been discharged. In most instances in Massachusetts, as in Ohio, the mills have found little difficulty in adjusting the eight-hour day of children under sixteen to the usual working day of ten hours, which holds for the other workers. In the second place, the hardships in individual families brought about by this change have been almost negligible.

It would be surprising indeed if some little hardship did not come to a few in order that large numbers might be benefited. It is inconceivable that any one can seriously believe that the health and general welfare of children between fourteen and sixteen years of age can be improved by putting them back into the mills and shops for two hours longer each day. Even in the exceptional case where the strongest boy of fifteen may not be harmed by ten hours' work a day, he is probably better off with eight hours' work and some play, with the opportunity of putting some of his energy into study or industrial education.

Children under sixteen should not work more than eight hours a day. The bills which seek to repeal or modify the eight-hour law for children under sixteen should be defeated.

MEDICAL LEGISLATION. REGISTRATION OF VITAL STATISTICS.

THERE is at present pending before the Massachusetts General Court a bill providing that the registration of vital statistics in this Commonwealth be placed in charge of the State Board of Health. This work is at present done by local authorities in each community, often a city or town registrar. The State Board of Health must then coördinate this information for its own use, with resultant inaccuracy and duplication of labor.

"The present bill provides in the first place that the State Board shall have charge of the registration of births, marriages and deaths in the state, shall assume the administrative work necessary to do this, including the way in which it shall be done, shall designate the forms and blanks to be used, and have authority to enforce the law throughout the state in a thorough and uniform manner.

"It is proposed to create under the State Board a director to be named state registrar of vital statistics, and registration districts are provided, the same to be the different cities or towns. The act further provides a penalty for the registrar in any district who shall in the judgment of the State Board fail or neglect to discharge efficiently the duties of his office or

who shall fail to make promptly the required returns."

Massachusetts is one of the few registration states where vital statistics are not lodged primarily in the hands of the State Board of Health. It seems eminently desirable that this anachronism should now be corrected.

MEDICAL LEGISLATION. DISCLOSURE OF PROFESSIONAL INFORMATION.

THERE is at present pending before the Massachusetts General Court, and now under consideration by the Committee on Judiciary, a bill to prevent the disclosure of professional information by physicians and nurses on the witness-stand, "unless such information indicates that the patient has been the victim or subject of crime." This raises again the old question of the admissibility of privileged medical communication as testimony and of the sanctity of *sub sigillo* statements. In point of practise, expert evidence in court is largely concerned with matters of fact and opinion, and seldom involves the quotation of hearsay. The status of the medical expert is still far from satisfactory, but it does not appear that this bill would in any way amend it. It seems better that physicians, like other witnesses, should be required to answer all questions allowed by the court, and that the court should exercise discretionary jurisdiction as to what questions may be asked, and as to the proper application of the evidence.

MEDICAL NOTES.

POSTPONEMENT OF ACTION ON RADIUM CONSERVATION.—In the issue of the JOURNAL for Jan. 29 (p. 176) we commented editorially on the Foster Radium Conservation Bill, then pending before the United States House of Representatives. The Rules Committee of the House decided on Feb. 5 not to allow the House to take up this measure at the present session. A similar measure, however, the Thomas Radium Conservation Bill, is still under consideration by the Miners' Committee of the Senate.

LONDON DEATH-RATES IN DECEMBER, 1913.—Statistics recently published show that the total death-rate of London for December, 1913, was 14.9 per 1000 inhabitants living. Among the several districts and boroughs the highest rate was 19.7 in Shoreditch, a crowded east-side slum; and the lowest was 11.0 in Lewisham, an open southern suburb.

A LIVING BRITISH CENTENARIAN.—Miss Ritso, of Bath, England, is said to have been born on Jan. 26, 1812. Her parents were both centenarians.

BOSTON AND NEW ENGLAND.

TWO CENTENARIANS.—Mrs. John Y. Belyea, who died in Upton, Mass., on Feb. 15, is said to have been born on May 24, 1808, at St. Johns, N.B. She was married in 1833, but had been a widow since 1880. She migrated to the United States in 1891. She is survived by one aged daughter.

Mrs. Kate Montosky, who died at Collinsville, Conn., on Feb. 17, is said to have been born on Sept. 14, 1810, in Russia. Her health was exceptionally good until recently.

LAWRENCE GENERAL HOSPITAL.—The recently published thirty-eighth annual report of the Lawrence (Mass.) General Hospital and Children's Home records the work of those institutions for the year ended on Sept. 30, 1913. During this period a total of 3800 patients were treated in all departments of the hospital, including 165 obstetric cases. Eight nurses were graduated from the training-school.

HOSPITAL BEQUEST.—The will of the late Catharine E. Galvin, of Watertown, Mass., who died on Jan. 15, was filed on Feb. 16, in the probate court at East Cambridge, Mass. It contains a bequest of $2000 to the Carney Hospital, South Boston.

NEW YORK.

O'LOUGHLIN MEMORIAL.—A new emergency ward in St. Vincent's Hospital, designed as a memorial to Dr. Francis N. O'Loughlin, the senior ship surgeon of the White Star Line, who lost his life in the disaster to the Titanic, was dedicated to the use of disabled seamen on February 16. Dr. O'Loughlin was a constant visitor to St. Vincent's, in attendance on injured sailors, and at the exercises the principal address

was made by Dr. Edward C. Titus, for many years an associate of his.

RADIUM INSTITUTE OF AMERICA.—At a meeting of the Radium Institute of America, held at Columbia University on Feb. 17, papers were read by Prof. George B. Pegram, Prof. William Duane of Harvard, Francis C. Wood, director of cancer research, Columbia University, and others. The principal address was made by Dr. Robert Abbe of New York, who was among the first investigators to make practical use of radium, and in it he announced that he had just received a report from Dr. Alexis Carrel, who, at his request, had been making researches at the Rockefeller Institute, and that this report had convinced him that the manner in which he had been applying radium in the treatment of malignant and other growths was wrong. The experiments of Carrel had demonstrated that the gamma rays, which had been depended upon for stopping cellular growth, were almost entirely inert, while the beta rays, which had been considered of little or no value, were extremely active in this respect. "His (Carrel's) experiments," said Dr. Abbe, "are only just beginning. Where they will end I will not attempt to forecast, except to suggest that within five years from now we will know vastly more about radium than we know at this time. . . This new method of studying the isolated rays emitted by radium will end our period of confusion as to the qualities of each ray. I know that the action of each ray is different from the others, but more work under Dr. Carrel's cautious hands and on the part of others will be needed before we can assign to each division of the isolated rays its exact rôle."

INOCULATION FOR TUBERCULOSIS.—At a recent meeting of the City Board of Health a resolution was adopted denying the application of Dr. Hans Karfunkel for permission to inoculate living cultures of an unidentified bacillus in the treatment of tuberculosis. Some time ago Dr. Karfunkel, who is from Berlin, made the application referred to, and, in compliance with the rule of the board, he described in full the manner of using the vaccine and submitted a culture for examination. He stated that the culture was originally obtained from an abscess developed in a patient after inoculation with Piorkowski's vaccine, and subsequently the same living organism was said to have been found in other vaccines used for the treatment of tuberculosis. Examination at the Research Laboratory, however, showed that the organism was in no way related to the tubercle bacillus, but that it belonged, in fact, to the group of spore-bearing bacilli of which the hay bacillus is the main type.

DEATH-RATE FOR WEEK ENDING FEB. 14, 1914.—There were 1553 deaths and a death-rate of 13.88 per 1000 of the population reported during the past week, against 1732 deaths and a rate of 16.82 for the corresponding week of 1913, a decrease in the absolute number of deaths of 179, equivalent to a decrease in the relative number of deaths of 313—and a decrease of 2.94 points in the rate.

The following causes showed an increased mortality: Measles, scarlet fever, diphtheria and organic heart diseases; typhoid fever and cerebro-spinal meningitis were accredited with the same number of deaths as in the corresponding week of 1913. The following causes showed a decreased mortality: Whooping cough, influenza, bronchitis, lobar pneumonia, bronchopneumonia, pulmonary tuberculosis, other forms of tuberculous diseases, Bright's disease and nephritis, diseases of the nervous system and violence.

The number of deaths reported during the week of infants under one year of age was 226, which was 72 less than in 1913; the number of deaths of children under five years of age was 348, a decrease of 110 deaths; from five to sixty-five years there was a decrease of 54 deaths, and at sixty-five years and over a decrease of 15 deaths.

The death-rate for the first seven weeks of 1914 was 14.61 per 1000 of the population as against a rate of 14.98 for the corresponding period of last year.

THE USE OF COMMON CUPS, TOWELS, AND FORKS.—Attention having been called to the fact that the Board of Health regulations with respect to common drinking cups and roller towels, are not being observed as they should be, Commissioner Goldwater is taking steps to secure fuller compliance with the department regulations. Letters have been sent to those found violating the sections of the Sanitary Code with respect to drinking cups and roller towels, warning them that a continuance of the offense will render the offender liable to arrest and prosecution.

In this connection, it may be stated that the department is also contemplating action against the use of common forks at the saloon free lunch counters. Investigation has shown that forks, used by one person in eating from a common dish of some food, such as hash, potato salad, sauerkraut, etc., are returned after using, to a glass containing some cold water only, to be picked up and used in the same way by succeeding persons. This very personal tool thus comes into more or less intimate contact with the saliva of the mouth and the mucous membrane of the tongue and lips.

In view of the fact that disease-producing bacteria, some of them a most virulent kind, may be present in secretions of the mouth and throat, it is deemed important to prohibit this common use of such eating utensils. In an examination of the common bar-room fork, undertaken sometime ago in Louisville, disease germs were found in thirteen out of sixteen specimens examined. It is suggested that the food at such lunch counters be prepared beforehand in the form of sandwiches, etc., and handed out to the individual, or else each customer be given food on a plate with individual utensils and that these utensils be thoroughly washed after using.

SMALLPOX AT NIAGARA FALLS.—On Feb. 1, there were 130 cases of smallpox at Niagara Falls, N. Y. If the epidemic continues, it may become necessary to isolate the entire town.

SALE OF BICHLORIDE TABLETS.—In last week's issue of the JOURNAL we commented editorially on legislative regulation of the sale of bichloride of mercury tablets. On Feb. 17 a regulation was adopted by the New York board of health, providing that after March 1 bichloride of mercury tablets may be sold at retail only on prescription of a physician.

9. GREENWALD, M. *Clinical Observations of Auscultation at the Acromion Process.*

4. Wagner reports a small number of cases of amebic dysentery successfully treated with emetine hydrochloride. He finds the action of this drug specific in this disease. It should be given, he says, in gr. ½ doses hypodermically daily for seven days. The effect is immediate and pronounced, and no untoward symptoms are observed. As recurrence may occur, a repetition of the treatment is advisable. The administration of emetine is a useful test in the diagnosis of diarrhea of obscure origin; if the condition is relieved it is proved to be amebic dysentery. [L. D. C.]

12. GARDNER, J. A., AND SIMPSON, B. T. *The Relation of Multiple Adenomata to the Etiology of Enlargement of the Prostate Gland.*

1. Lambert suggests cardioplasty as the operation for the relief of diffuse dilatation of the esophagus. Cases resulting from cardiospasm can be permanently

cured this way. In these cases the esophagus is found to be lengthened as well as dilated. The operation is by the abdominal route, after a preliminary gastrostomy.

2. Clark and Keene show by excellent diagrams the close and important relationship between pelvic disease in the female and diseases of the urinary system. They urge routine cystoscopic examination in all cases presenting vesical symptoms.

3. Bloodgood's article is of the type which is of extreme importance to surgeons in educational work for the general practitioner.

4. Leonard believes that the presence of a marked endocervicitis should be considered as a contra-indication to trachellorrhaphy. Post-operative hemorrhage occurs in about 5 per cent. after amputation of the cervix, but very rarely after thachellorrhaphy, the improvement in symptoms after the latter operation being as great as that from the former. Trachellorrhaphy, unlike amputation of the cervix, is not a curative operation for endocervicitis. Fertility is much more likely to follow trachellorrhaphy than amputation of the cervix, which latter is more liable to be followed by abortion than the former, which has no effect on subsequent pregnancy. Labor after amputation may be very difficult, while normal after trachellorrhaphy. Trachellorrhaphy then is the operation of choice in women of child-bearing age.

5. Boorstein's article on syphilis of bones is well illustrated by case reports and plates.

6. Sulig and Tobolske advocate and plainly explain the inguinal route for cure of femoral hernia.

[E. H. R.]

THE QUARTERLY JOURNAL OF MEDICINE.

1. *WARRINGTON, W. B. *Intracranial Serous Effusions of Inflammatory Origin. Meningitis or Ependymitis Serosa—Meningism—with a Note on "Pseudo-tumors of the Brain."*
2. *ELLIOTT, T. R. *The Experimental Formation of Acute Gastric Ulcers.*
3. *GASKELL, WALLIS, SLADDEN, VAILE AND GARROD. *A Contribution to the Study of Bronzed Diabetes.*
4. *GIBSON, A. G. *On the Infective Nature of Certain Cases of Splenomegaly and Banti's Disease.*
5. *COWAN, HARRINGTON, AND RIDDELL. *On Pneumopericardium.*
6. GOETSCH, E. *Critical Review: The Pituitary Body.*

1. Warrington discusses in a thorough and interesting manner the pathology and symptomatology of serous effusions within the skull, illustrating his remarks with case reports. These effusions may be acute or chronic. The acute cases, the serous meningitis of Quincke, are most often secondary to a septic focus, usually in the ear. The division between "meningism" and meningitis serosa, on the one hand, and between the latter and purulent meningitis, on the other, is not sharp and distinct, but gradual. The examination of the spinal fluid furnishes the most important distinction. In meningism it is normal, except for increased pressure, which is usually present. (The pressure is often normal.—W. T.) In meningitis serosa the fluid shows inflammatory signs, such as increased protein, increased cell counts, but micro-organisms are usually absent and the fluid is clear. In the chronic cases the symptoms and signs are those of increased intracranial tension, due to an acquired internal hydrocephalus. In these patients the erroneous diagnosis of tumor of the brain is often made, and indeed the differential diagnosis is very difficult. They frequently recover after a decompression, usually with some permanent impairment of vision.

2. Elliott has discovered that acute ulcers of the stomach may be produced in guinea-pigs with great regularity by subcutaneous injection of the substance tetrahydro-B-naphthylamine hydrochloride. The first change appeared in one hour after the injection, and consisted of necrosis of the surface epithelium, often accompanied by small hemorrhages into the mucous membrane. Within 24 hours the ulcers are fully developed, extending down to the muscularis mucosae. They healed with great rapidity unless they became infected. Guinea-pigs that were deprived of food before and after the injection, did not develop ulcers. Chronic ulcers could not be caused by this method. The writer concludes that the ulceration is due to the action of the gastric juice on the damaged mucous membrane. Acute gastric ulcers in man are probably often caused in a similar way by the combined action of the gastric juice and toxic substances.

3. This article contains a careful study of the urine, feces and blood, and the autopsy findings in a typical case of hemochromatosis, a condition in which cirrhosis of the liver and pancreas is accompanied by the deposition of pigment in the skin and internal organs, and in the later stages by diabetes. The most important facts brought out were with reference to the iron metabolism. The blood was found to contain an excess of iron, while the feces and urine contained no iron. In the kidney the interesting discovery was made that the convoluted tubules of the first order contained no iron, while those of the second order and the glomeruli showed large amounts. This suggests that the iron is excreted by the glomeruli, but is taken up again by the tubules of the second order. The hypothesis is advanced that the pigment is derived from nucleo proteins and not from hemoglobin.

4. Gibson describes structures found by him in sections of spleens in cases of splenomegaly, which he regards as parasites of the streptothrix family. He claims that these bodies are the cause of the splenomegaly, although he has observed them only in sections and has not cultivated them. The cases in which he found them included Banti's disease, chronic passive congestion and syphilis.

5. The writers publish a very interesting series of radiographs of a case of pneumopericardium uncomplicated by effusion. The cardiac dullness was not obliterated and the diagnosis was made possible only by x-ray examination. [W. T.]

THE PRACTITIONER.

JANUARY, 1914.

1. BENNETT, W. H. *Some Clinical Experiences in Deceptive Symptoms.*

14. PIKE, J. B. *Encapsulation as a Factor in Pathology.*
15. JOHNSON, R. *Kharga Oasis as a Health Resort.*

3. Gray believes that stomach-aches in childhood can be explained by interference with the normal passage of food through the intestine. Such interference may take place in three ways through abnormal conditions:—

1. In the lumen of the intestines.
2. In the intestinal wall.
3. In the mesentery.

Under the first heading he discusses cases of abdominal pain associated with diarrhea; under the second, those rarer cases associated with purpura, in which the chief and often only symptom is pain. Such pain may occur in tonsillitis, diphtheria and other conditions. Under the third heading he considers acute inflammatory conditions, such as appendicitis.

4. Pritchard, in a thoughtful article, considers in detail the physiology and chemistry of digestion and metabolism of infants. The paper is interesting, but not suited for review.

7. Thomson, basing his investigations on 500 cases of pulmonary tuberculosis, concludes in regard to the diazo- and Russo-reactions that (*a*) a persistent diazo-reaction or a combined diazo- and Russo-reaction in pulmonary tuberculosis of recent onset is a sign of serious significance; (*b*) the disappearance of the diazo-reaction is usually associated with general improvement; (*c*) a positive diazo-reaction with negative Russo- is less serious than the combined reactions; (*d*) these reactions mean severe systemic intoxication and contra-indicate the use of tuberculin.

The Russo-reaction consists in adding 2-3 drops of a 1-1000 methylin blue solution to a small quantity of urine in a test-tube. When positive, the solution changes from peacock blue to an emerald green color.

6. STRUTHERS, J. W. *Spontaneous Recovery after Perforation of Duodenal Ulcer.*
7. WILKIE, D. P. D. *Case of Osteochondritis Deformans Juvenilis.*

1. This article is full of practical information concerning the acute infectious diseases, their periods of incubation, isolation and quarantine. It presents nothing especially new, however.

2. McNeil discusses from various points of view the subject of status lymphaticus. He divides these cases into three groups: (1) Infants found dead in bed overnight, (2) older children or young adults succumbing during anesthesia, (3) young adults dying suddenly during bathing. He reviews the historical features of this strange condition and then takes up the age incidence, sex incidence, general appearance of the body in these cases and morbid anatomy. This latter he discusses in detail, with special reference to these lymph glands and tissues, suprarenals, thyroid, pituitary, and others. He presents the details of the findings in 13 cases of sudden deaths in infants. The article is carefully summarized, is provided with excellent plates and an elaborate bibliography. [J. B. H.]

13. SUDHOFF. *Julius Preuss.*

1. To gross appearances the skin lesions of typhus and typhoid fevers are very similar. Fraenkel has been able to excise the skin in two cases of typhus fever, to fix it immediately and to study the histological changes in the fresh tissue. In typhoid fever, there occurs a true lesion of the skin with collections of organisms and cells, leading to a pressure necrosis. In typhus fever, on the other hand, the small arteries of the skin are affected, with infiltration around them leading to peri-vascular nodules which result in characteristic gross appearances. Fraenkel believes that this lesion is peculiar to typhus, and serves as a means for making a differential diagnosis between the two diseases.

12. Oeller and Stephan give a thorough review of the literature which has accumulated on Abderhalden's dialysis method. The test has been applied in gynecology, psychiatry and internal medicine as a means for diagnosis. In the majority of pregnancy cases, placental tissue is split by a protective ferment in the blood. But the same reaction is obtained in a relatively large percentage of non-pregnant cases. In psychiatry, and in internal medicine, especially in diseases of internal secretion and tuberculosis, several observers have reported brilliant results from the test. Critical studies, however, show that the results obtained have not been specific for any one organ or for any definite type of disease, and therefore Oeller and Stephan feel that the method is not of any special value.

The difficulty with the observations recorded is their lack of proper control. Oeller and Stephan report experiments to prove this, and show how better controls should be made. They conclude that Abderhalden's method cannot be applied for general clinical use until the theory of protective ferments is established more soundly. [R. F.]

4. During 1913, seventy-one cases of infantile paralysis were seen in the Heildelberg clinic. Recent advances in the study of the disease have determined its etiology. One of the theories in regard to its transmission has been that the virus is carried by fowls on account of a disease in these animals which clinically is not unlike poliomyelitis. Lust and Rosenberg conducted experiments to determine whether fowl paralysis showed histological findings which resembled those of infantile paralysis, and whether fowls could be inoculated with the virus.

From their results Lust and Rosenberg concluded that hens were neither artificially or naturally prone to the disease, and that while hen paralysis may be caused by a filterable virus related to that of poliomyelitis, the diseases are not absolutely alike.

8. It is recognized that a certain degree of asymmetry is normal in individuals. Rarely hemihypertrophy or unilateral gigantism occurs when one side of the body develops to a much greater extent than the other. Dietlein reports such a case. There are various theories as to the cause of the overgrowth, certain authors believing that it is due to connective tissue hyperplasia, muscular hyperplasia, or nervous disturbances. None of these factors appeared to play a part in Dietlein's case. He believes that the condition was possibly due to a congenital hemi-elephantiasis caused by abnormal development of the veins on one side of the body. As proof of this was the fact that all the veins of the affected side were larger than on the other side. [R. F.]

Obituary.

ROSWELL PARK, M.D.

DR. ROSWELL PARK, who died on Feb. 15, at Buffalo, N. Y., was born on May 4, 1852, in Pomfret, Conn. He received the degree of A.B. from Racine (Wis.) College in 1872, and that of M.D. in 1876 from Northwestern University. From 1877 to 79 he was demonstrator of anatomy at the Women's Medical College, Chicago, and adjunct professor of anatomy at Northwestern University from 1879 to 82. In the latter year he became lecturer on surgery at the Rush Medical College, Chicago, and in 1883 surgeon to the Buffalo (N. Y.) General Hospital and professor of surgery at the University of Buffalo. In 1891 he published "Lectures on Surgical Pathology." In 1892 he received on honorary degree of M.D. from Lake Forest University, and in 1895 an honorary A.M. from Harvard. In 1896 he published his "Text-Book of Surgery," in two volumes, and in 1897 his "History of Medicine." In 1902 he received an honorary degree of LL.D. from Yale, and in 1907 published "The Principles and Practice of Modern Surgery." He was a former president of the American Surgical Association and of the Medical Society of the State of New York. He is survived by his widow.

Correspondence.

PAIN FROM FRONTAL SINUS DISEASE.

BOSTON, Feb. 20, 1914.

Mr. Editor: In the number of the BOSTON MEDICAL AND SURGICAL JOURNAL for Feb. 19th, 1914, page 283, there is a statement which seems to me to be incorrect. According to my experience, pain from frontal sinus disease begins in the morning and usually disappears or diminishes in the afternoon. Your editorial says that the headache comes on regularly in the afternoon or toward evening, which is certainly contrary to what is taught in all text books dealing with diseases of the nose.

Yours truly,

JOHN W. FARLOW, M. D.

Miscellany.

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE TWO WEEKS ENDING FEBRUARY 14, 1914.

January 21, Surgeon J. A. Murphy ordered to the *Michigan.*

February 2, P. A. Surgeon J. B. Mears, detached: *Cincinnati* to home.

P. A. Surgeon C. E. Strite, detached: *Michigan* to home.

February 3, Surgeon R. R. Richardson, to Naval Training Station, Great Lakes, Ill.

P. A. Surgeon F. H. Brooks, to Navy Yard, Norfolk, Va.

Asst. Surgeon J. J. O'Malley, to Naval Hospital, Norfolk, Va.

Surgeon H. E. Odell, to Naval Hospital, Canacao, P. I.

February 4, P. A. Surgeon E. O. J. Eytinge, detached: Naval Hospital, Mare Island, Cal., to treatment at that Hospital.

February 5, Surgeon C. N. Fiske, to Navy Yard, Mare Island, Cal.

P. A. Surgeon C. B. Munger, to Receiving Ship, Puget Sound, Washington.

P. A. Surgeon W. S. Hoon, detached: Mare Island Yard, to *Pittsburg.*

P. A. Surgeon W. H. Short, detached: Naval Station, Guantanamo, Cuba, to temporary duty Receiving Ship, Mare Island, Cal.

P. A. Surgeon F. W. P. Hough, detached: Insular Government, P. I., to *Cincinnati.*

P. A. Surgeon E. C. White, detached: Naval Hospital, Canacao, P. I., to home and wait orders.

February 7, Commissioned from:

Surgeon W. S. Hoon, from November 14, 1913.
P. A. Surgeon A. B. Davidson, from March 28, 1913.
P. A. Surgeon J. J. O'Malley, from October 8, 1913.
P. A. Surgeon R. F. Sheehan, from October 5, 1913.
P. A. Surgeon W. H. Halsey, from October 1, 1913.
P. A. Surgeon W. J. Riddick, from March 28, 1913.
P. A. Surgeon D. C. Walton, from March 28, 1913.
Asst. Surgeon W. W. Wickersham, from January 14, 1914.

February 12, Surgeon R. E. Hoyt, detached: *Michigan;* to sick leave.

P. A. Surgeon Heber Butts, detached: *Elcano* to *Wilmington.*

P. A. Surgeon Martin Donelson, detached: *Wilmington* to Naval Station, Iloagapo, P. I.

Asst. Surgeon R. C. Davis, detached: Naval Hospital, Canacao, P. I., to *Elcano.*

February 6, Medical Director C. F. Stokes, detached chief of Medicine and Surgery; to temporary duty in connection with that bureau.

Surgeon F. E. McCullough, to temporary assistant to Bureau of Medicine and Surgery.

Surgeon T. W. Richards, detached: Bureau of Medicine and Surgery, to fleet surgeon, Atlantic Reserve Fleet.

UNITED STATES PUBLIC HEALTH SERVICE.

EXAMINATION OF CANDIDATES FOR ASSISTANT SURGEON.

A board of commissioned medical officers will be convened to meet at the Bureau of Public Health Service, 3 B Street, S.E., Washington, D. C., on Monday, March 9, 1914, at 10 o'clock a. m., for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health Service. Examinations will be scheduled to be held at other stations of the Service at a later date.

Candidates must be between 23 and 32 years of age, graduates of a reputable medical college, and must furnish testimonials from two responsible persons as to their professional and moral character, one preferably being from a Doctor of Medicine.

For invitation to appear before the board of examiners, address "Surgeon General, Public Health Service, Washington, D. C."

NOTICES.

MASSACHUSETTS GENERAL HOSPITAL.—A surgical meeting open to the medical profession will be held at 8.15 p. m., Friday, Feb. 27, 1914, in the lower amphitheatre of the Out-Patient Department. Entrance on either Blossom or Fruit Streets.

Dr. Channing C. Simmons will present "Treatment of Osteomyelitis."

Dr. Beth Vincent will present "Choice of Methods of Technic in Transfusion of Blood."

THE HARVEY SOCIETY. — The ninth lecture will be delivered on Saturday, February 28th, at 8.30 p. m., at the New York Academy of Medicine, 17 West 43d street, by Prof. Richard P. Strong, Harvard University.

Subject: "The Etiology of Oroya Fever and Verruga Peruviana."

THIRD INTERNATIONAL CONGRESS ON OCCUPATION DISEASES.—The undersigned committee has been organized for the purpose of inviting the attention of the Medical Profession and all others interested in the prevention of Occupational Diseases to the Third International Congress on Diseases of Occupation to be held in Vienna in September, 1914.

Among the topics which will be considered at the coming Congress are:

1. The physiology and pathology of fatigue, with special reference to vocational work and to the effects of night work on the nervous system.
2. Work in hot and damp air.
3. Occupational Anthrax
4. Pneumononiosis.
5. Injuries caused by electricity.
6. Industrial poisons.
7. Injuries of hearing caused by industrial pursuits.
8. Miscellaneous communications.

SOCIETY NOTICES.

BOSTON SOCIETY OF MEDICAL SCIENCES.—The Boston Society of Medical Sciences announces a meeting of the Harvard Medical School Historical Society (Wm. J. Kerr, Secretary), on Tuesday evening, March 3, 1914, in the amphitheatre of the Peter Bent Brigham Hospital, at 8.15 o'clock. Program:

Dr. Fitz: "Caleb Hillier Tarry on Exophthalmic Goitre."

Dr. Walton: "Medical Saints in Art" (illustrated).

Dr. W. S. Thayer: "Notes on Cotton Mather."

THOMAS ORDWAY, *Secretary and Treasurer,*
Harvard Medical School.

APPOINTMENTS.

The following appointments to the Medical Staff of the Boston Dispensary have been made: Dr. John H. Bufford, Physician in the Dermatological Department; Dr. W. G. Funnell, Assistant Surgeon in the Eye Department; Dr. J. H. Blaisdell and Dr. Harold W. Dana, Assistant Physicians in the Dermatological Department; Dr. Leroy A. Luce, Physician in the Electrical Department; Dr. W. L. Quennell, Dr. Edward Martin, and Dr. Samuel G. Paolo, Assistants to the Physicians in the Children's Medical Department.

RECENT DEATHS.

DR. HORACE EUGENE MARION, a Fellow of The Massachusetts Medical Society, formerly chairman of its Committee on Medical Diplomas, Medical Director of the 2d Brigade, M. V. M., died in his automobile of heart disease at Boston, February 8, 1914, aged 70 years. He was a native of Burlington, Vt., and a graduate of Dartmouth College with the degree of B.S. in 1866 and M.D. in 1869. He had lived and practised in Brighton since 1870. He was a member of the Obstetrical Society of Boston and was much interested in Masonic and G. A. R. affairs.

DR. ALBERT H. TOMPKINS, who died recently in Jamaica Plain, was born at Little Compton, R. I., in 1844. He received the degree of M.D., in 1875 from the Boston University Medical School. He was a member of the American Institute of Homeopathy and of the Massachusetts and Boston Homeopathic Medical Societies. He is survived by his widow and by one son.

DR. CLAUDIUS L. HOYT, who died of nephritis recently in Manchester, Mass., was born at that town in 1851, and had practised dentistry there for many years.

DR. STANLEY HOWARD MACGILLVARY, of Brooklyn, N. Y., died on February 16 at St. Mary's Hospital, after an operation for appendicitis. He was a native of Sydney, Cape Breton Island, and 45 years of age, and was graduated from Bellevue Hospital Medical College, New York, in 1890.

DR. WILLIAM KELLY SIMPSON of New York, professor of laryngology in the medical department of Columbia University, died from cerebral apoplexy on February 6. He was born in Hudson, N. Y., on April 18, 1855, and was graduated from Cornell University in 1876 and from the College of Physicians and Surgeons, New York, in 1880. He served as interne at the Presbyterian Hospital, and after engaging in private practice became well known as a specialist in diseases of the throat, ear and nose. At the time of his death Dr. Simpson, in addition to his professorship at Columbia, held the positions of laryngologist to the Vanderbilt Clinic, consulting otologist to the Presbyterian Hospital, and consulting laryngologist to Seton Hospital, the New York Foundling Hospital, St. John's Riverside Hospital, Yonkers, and Somerset Hospital, Somerville, N. J.

-1914 brary

Address.

RELATION OF THE GENERAL HOSPITAL TO THE TRAINING SCHOOL FOR NURSES.*

BY HENRY M. HURD, M.D., BALTIMORE.

THE history of the training school movement in the United States is most instructive. Among the first schools in this country were those at Bellevue Hospital, at the Massachusetts General Hospital, at the New Haven Hospital, at the Philadelphia Hospital and later at the Illinois Training School. All were separate organizations endowed and organized by philanthropic women which had contractual relations with their respective hospitals, but were in no sense a part of the hospital. They were under contract to furnish a certain number of nurses to do the nursing work of specified wards, but the hospital itself felt no responsibility for the management of the school and in fact any effort on the part of the hospital to control the school was evidently resented by those who had charge of it. This was largely due to the fact that the organization of schools in this country to educate and train nurses, especially women nurses, had been regarded a dangerous experiment by conservative members of the medical profession. Training schools had a standing very much like that of the "votes-for-women movement" just now. They were still in the marching stage. They had their faces set towards the promised land but had not arrived. For this reason the ladies who were interested in the organization and devedopment of training schools were compelled to organize them without assistance from hospital authorities, as separate and distinct institutions. This was unfortunate, because it engendered a spirit of mutual criticism which continued for a long time between hospital officers and those who were managing training schools. Hospital officers and physicians under the circumstances were quick to criticise the management of the schools and to exaggerate deficiencies and short-comings even when they did not altogether condemn the whole scheme as impracticable. On the other hand boards in charge of training schools were equally inclined to criticise hospitals and to assert that if the management of them could be committed to the training schools, the care of the sick would thereby be much facilitated, and all administrative difficulties would disappear. We hear such statements from excellent women even at this day. I do not complain of the spirit of antagonism between training schools and hospitals —it was inevitable—and I only mention it to show why after a time it became absolutely essential that the school and the hospital should be more closely related. The jealousies, antagonisms and needless criticisms which hampered the work of both hospital and training school finally led a wise and far-seeing medical man, Dr. Edward Cowles, then superintendent of the Boston City Hospital, to organize a training school in that Hospital, under its control and not under a separate board of lady managers. The advantages of such identity between the school and the Hospital proved so great that it has become the ordinary relation between hospitals and training schools; the training school being now considered an indispensable and integral part of every hospital.

Of the early training schools which I mentioned in the beginning of this address, but one remains in a state of single blessedness. The rest have been wooed and won by hospitals. The Illinois Training School connected for a quarter of a century or more with hospitals in the city of Chicago, has been under the control of a wise and liberal board of lady managers from its organization, and has maintained its autonomy. I prediet, however, that the time will come when its management will see the importance of a closer relation than that of friendship with a good hospital to secure greater opportunities for the school and greater efficiency in its work.

It is not strange that the mutual advantages of a union between the training school and the hospital have been apparent in every city where it has been tried. An organic relation has brought about a good understanding between the management of the hospital and the superintendent of the training school so that the latter has been responsible for the selection of nurses and the hospital has appointed them. It has afforded better opportunities for training because the work has been carried on through the mutual efforts of the superintendent of the hospital and the superintendent of the training school. Pupil nurses have not found themselves in the hospital as a matter of privilege exposed to the criticism of unfriendly medical men but have become a part of the hospital machinery. Consequently the nurse has a better standing and larger opportunity to secure a thorough efficient training. This better relation between the two has also brought a recognition of the duty of the hospital to train its nurses and thus to contribute materially to the welfare of the community and to the health of the whole city.

In the vast majority of general hospitals, therefore, and in such other hospitals as are not under the control of religious orders the training school for nurses has become an integral part of the hospital and receives the same recognition as any other portion of the hospital. In fact in many hospitals it is conceded that the mission of the hospital is not only to take care of the sick, and to promote the training of medical men in its wards as internes, but also to

* Read at the graduating exercises of the Massachusetts General Hospital Training School for Nurses, January 15, 1914.

foster the training of young women as nurses. For the future there seems no reason why the training school and hospital authorities everywhere through the country should not walk hand in hand in an effort to promote the better training of nurses and better care of patients.

While I would not seek to minimize the great advantage to the training school and to the hospital of this mutual relation, candor compels me to acknowledge that the union of the two has not at all times and in all places been an unalloyed benefit, and it is not now. I cannot disregard the patent fact that many small hospitals and special hospitals have taken advantage of this relation to exploit the training school for the benefit of the hospital. Such exploitation has generally occurred because of the discovery that a training school for nurses was a valuable asset to a hospital. It not only advertised the hospital as better than one which did not possess a training school, but also enabled the proprietor of the small special hospital often times to procure a nursing service at a cheaper rate than would be possible in any other manner. This has led to the organization of training schools in many hospitals where a training school ought not under any circumstances to exist. Take a single example, and there are many such, of a small hospital interested solely in the surgical diseases of women, owned and operated as a private enterprise. Such a hospital in the interest of nursing has no right to organize a training school. After a period of special service the nurses graduate and become so-called trained nurses in the community to encounter active and acute diseases with which they have had no experience and to cope with the emergencies which may arise in the treatment of such cases. This has been done I am sorry to say in too many instances with the effect to lower the standard of nursing and has led to an imperfect fulfilment of the duty which the hospital owes to the pupil nurse in a variety of ways. It is unjust to the nurse and a fraud upon the public. Practical nursing has not been well taught because the special hospital has not had material enough to permit the nurse to receive instruction in the various branches of nursing.

It soon became apparent to those who were thus conducting special hospital training schools that the best women did not care to come to them for training, because they were not eligible to registration under the laws of states in which the duty of the public toward well-educated nurses had been scrupulously considered. It consequently became necessary for special hospitals, in order to carry out their original plan to train pupil nurses, to accept persons for training whose educational qualifications fell below the proper standard. The result has been the graduation of many persons not fitted by education or training to assume the duties which naturally devolve upon a trained nurse. In many instances nurses not old enough to commence training, who had not received sufficient education prior to entering upon the study of nursing, after an inferior course of study were sent out to serve the community with imperfect ideals as to nursing and an inadequate training in its different branches. This has discouraged applications on the part of capable women who in the better schools must spend three years of their time to secure training in a good hospital in addition to several years already spent in procuring a preliminary education. These women, superior women, I think we can call them without flattery, are unwilling to spend time and effort in the arduous labors of a training school of the higher grade to find themselves as graduate nurses in unfair competition with imperfectly educated women, with aims and ideals far below those of a well educated nurse. This is the reason why we hear complaints that hospitals find it difficult to procure pupil nurses for their training schools. I have already alluded to the attempt which has been made in some quarters to meet the difficulty by lowering the standard of educational requirements for nurses. It has even gone beyond this. Not only has the educational standard been lowered but the age and health of those selected for training have often not been considered, until finally there is danger that the educated nurse will not be fit either physically or by age as well as by education to assume her difficult and trying duties. Many persons seem to forget, or at least to lose sight of the fact that the training school for nurses is a school, that pupil nurses should be treated in all respects as students in other schools and admitted to courses of training only when they are fitted to enter upon the study of nursing. The training school is an educational institution connected with a hospital, precisely as a medical school is a school similarly connected with a hospital, and neither of them can be treated as an economic device to secure cheaper nurses and cheaper medical men. A moral compulsion consequently ought to be exercised on all hospitals both from without and within to establish and maintain good training schools with proper educational standards in the interest of better nursing, rather than in the interest of economy to the hospital. The best hospitals do not always take perfect care of their patients, nor do the best training schools always turn out perfect nurses. They do the best they can with the best persons attainable. Hospitals for their own good and that of the state and the public cannot afford to foster the production of inferior nurses simply because they are more easily procured and less costly to train. Such schools are not cheap in the long run, nor do they permanently benefit the hospital, because they ultimately prevent the best women from entering the profession of nursing.

An entrance requirement therefore would seem essential for every pupil nurse. The hospital has a right and duty to fix an educational entrance requirement as much as a health requirement, and in its turn should give a good,

thorough honest course of instruction. To attempt to get something for nothing is an economic error which sooner or later will destroy all ideals of nursing and lower the standards of all training schools. The interests of the hospital and of the school are identical. Every pupil nurse has a right to a first-class training, and every hospital has an equal right to expect that women of education and refinement will apply for appointments as pupil nurses and will avail themselves of the opportunities afforded by a proper training school. I am persuaded in fact that every training school which has a good preliminary educational requirement and gives pupil nurses reasonable hours of labor with due recognition of the severity of the work, and a thorough and sensible course of instruction will not lack for pupil nurses. I repeat that they will not lack for nurses if proper attention is paid to the health, welfare and education of pupil nurses, because it is evident to all who have anything to do with training schools that educated women of the right stamp are as anxious to enter the profession as ever. Many have been deterred from doing so by the fact that the well educated nurse after years of study and training, found herself obliged to compete with nurses who had not received similar advantages. She had no protection from half-educated or unscrupulous competitors.

After much thought, I have come to the conclusion that every hospital should educate two classes of attendants upon the sick, one to be known as trained nurses and the other as trained attendants. The trained nurse should be guaranteed her proper position as a nurse under a state registration and the right to maintain her privileges by an appeal to the courts if need be. The semi-trained nurse should be called an attendant upon the sick, her duties, privileges and right should equally be fixed by law. In the U. S. Army medical corps the surgeon is never confounded with the hospital steward, nor do we find the hospital steward arrogating to himself the duties and responsibilities of the army surgeon. Similarly in the world at large as at the hospital, the trained nurse should occupy a higher position and be in no danger of competition from the untrained woman. The key to the whole situation is an adequate registration law for nurses.

The laws of every state should recognize the legal status of the nurse earned by virtue of the hard work which she has done and should protect her in her rights. This is not trade unionism as some people claim, but simple justice and it is the duty of hospital men to make every effort to supply this protection to nurses who have come to us in good faith and who have done their duty thoroughly and conscientiously for three years. Hospitals or individuals should not allow considerations of economy to impair faithful work.

When in an adjoining state the superintendents of prominent hospitals in a communication to the State Department of Education expressed the conviction that it was essential to lower the standard of educational requirements for nurses in order to educate nurses for the service of the public, one cannot help feeling that they acted hastily and without fully appreciating the consequences of their act.

The lack of nurses complained of by these gentlemen was more the lack of pupil nurses in the hospitals than of trained nurses in the community at large. There is in fact little scarcity of trained nurses in any community. There may be a scarcity of good nurses simply because the profession of nursing has been flooded with nurses of insufficient education, who had been accepted for training on similar pleas or turned out from correspondence schools. If those who are thus charitably interested in supplying nurses to the public will call to mind the large numbers of nurses ready in every city to serve the public but finding difficulty in getting cases, they must confess that the lack of nurses of which they complain cannot be a crying evil. Nurses ought to be protected in the rights which they have earned for themselves precisely as physicians and lawyers are protected. Physicians cannot practice unless they have had a certain degree of education and can fulfill certain professional and educational requirements. A lawyer is not admitted to the bar until he can show that he has spent a specified time in the study of his profession and has done a prescribed amount of work. In Maryland undertakers and barbers even are required to be examined and licensed. Similar care should be taken to supply to the trained nurse the protection of the law. To this I may add a statement which has doubtless occurred many times to all of you. The welfare of both hospital and nursing profession alike is irrevocably bound together. The hospital cannot do its work thoroughly and meet the requirements of the modern hospital treatment of the sick without the help of the trained nurse. Trained nurses on the other hand cannot receive their proper instruction except in a general hospital and in a training school managed and controlled by the hospital authorities.

The time is past, far past I hope, when any one can propose that the training school should be divorced from the hospital and placed as formerly under the control of a separate organization. I go farther than this, in fact, because I believe in order that nurses may enter upon the higher education which now seems to be required by every nurse, to fit her for calls to better and larger service, it is essential that higher schools of instruction also be connected organically with hospitals. The good work of Teachers College in New York needs to be supplemented by a closer connection with a hospital. The incentive to education which comes with the grouping together of large bodies of young women in the training school and in the hospital wards must not be overlooked. Trained nurses have

done much for hospitals and hospitals in turn have done much for nurses. It is impossible for any one to "assess" the mutual benefits, to use a legal phrase.

I now come to the most pleasing duty of my address (I do not allude to giving advice) and I feel it not so much a duty as a pleasure to welcome you as nurses to the great band of nurses who have gone before you. The leaders of this band who obtained their education twenty-five or thirty years ago, were few in number but mighty in faith and the onward march of those who have followed them in constantly increasing numbers has justified the correctness of their vision. Numbered at first by tens and by scores, they now see their successors numbered by thousands.

I congratulate you upon the completion of your chosen work. You have labored long and zealously and have attained the honor for which you have striven. A diploma is not much in itself, a mere piece of parchment with some stately unfamiliar words written or printed upon it. It is related that Thoreau the naturalist once in writing of the diploma which he had received from Harvard University, uttered the bitter gibe "In future let every sheep keep his own skin; I wish none of it," and so he might if the sheepshin or parchment constituted the whole of the diploma. It is not the parchment itself, after all which you prize but it is what it signifies. Ingersoll once said that a bill of fare is not a dinner. True enough, but it may be the *promise* of a dinner just as this piece of parchment gives promise of an educated nurse, of one who by study and toil and training of the head, hand, mind and heart has fitted herself to undertake the most serious of all callings. I always enjoy reading the vigorous outline which Florence Nightingale gave of her conception of what a nurse ought to be. She believed that the object of training was to teach not only what was to be done but how to do it. The physician or surgeon should order whatever needs to be done for the patient's care, but the training of the nurse should teach her how to do it to his order. Training must also teach the symptoms of disease so that the nurse may know what certain symptoms indicate about any disease and whether the patient is worse or better when the symptoms change. *Telling the nurse what to do* is not enough and cannot be enough to make her work perfect. To use Miss Nightingale's words, "The trained power of attending to one's own impressions made by one's own senses, so that these should tell the nurse how the patient is, is the *sine qua non* of being a nurse at all." It is not sufficient to use "the sense you have got." The nurse's eye and ear, her smell and touch and even her taste are all to be trained and all may be as necessary to the welfare of her patient as her head. The nurse should be trained to observe, in fact her powers of observation require training. As Miss Nightingale says "Merely looking at the sick is not observing. To look is not always to see. It needs a high degree of training to look, so that looking shall tell the nurse aright, so that she may tell the medical officer aright, what has happened in his absence. Observation tells the nurse how the patient is, reflection tells what is to be done; training tells how it is to be done. Training and experience are of course necessary to teach us too, how to observe, what to observe, how to think, what to think. Observation tells us the fact; reflection the meaning of the fact. Reflection needs training as much as observation." These terse sentences go to the root of the whole theory upon which she wrought in her training of nurses.

In the light of her illuminating words how trivial and childish appear the objections which we hear to the so-called over-educated and overtrained nurse and the laudation heard even now in the year of Our Lord 1914, of the natural born nurse who "mothers" her patients, who needs no training and who only follows her heaven-born impulses and her womanly intuitions.

The first and foremost ideal in the mind of every one is clearly that of self-sacrifice. In your chosen calling you subordinate inclination to duty and become absorbed in the development of a purpose of personal service. This motive consecrates your work and gives it a human touch. Nursing without it is mechanical; with it you become transformed into ministers of mercy and find the fullest scope for enthusiasm and self-devotion.

Another ideal allied to it which is developing rapidly is that of helpfulness to the community. We find trained nurses now in great demand as school nurses, tuberculosis nurses, visiting nurses orthopedic nurses, and mothers'-relief nurses, nurses in charge of milk stations, social service workers and settlement nurses. Those who enter upon work of this character do so at much sacrifice of money and personal comfort. They could do "better for themselves," to use a popular phrase, if they devoted their time to private nursing, but they cannot disregard the call of the common weal and they forsake ease and the call of a good time to carry the gospel of health to the ignorant, the poor and the suffering. All praise to them! They are practically paying the debt which we all owe to the suffering poor. We owe it but they pay it.

There are compensations to the nurse for her life of self-sacrifice and her spirit of helpfulness. She becomes self-reliant and gains a mental poise, a breadth of sympathy and steadiness of purpose which are granted to but few. I need not urge you to cherish these ideals and cultivate their growth.

In receiving your training you have acquired new ideals of life and of personal service. You have the *esprit de corps* of your chosen profession. This represents a body of sentiment which has been growing in your minds for three laborious, but I trust, happy, years—somewhat, possibly as a result of the traditions which you have

inherited from those who have gone before you but unquestionably much more because of the growth and development of your own hearts, minds and characters during training. You have caught the spirit and received the baptism of new emotions, ideals and aspirations. I welcome you to the profession of nursing and I bid you God speed.

THE RELATIONSHIP BETWEEN EPILEPSY AND MIGRAINE.*

By George A. Waterman, M.D., Boston,

Instructor in Neurology, Harvard Medical School; Associate Neurologist, Massachusetts General Hospital.

Epilepsy resembles migraine in many of its aspects. Both occur with great frequency as a direct inheritance from the family of either parent. Both recur with more or less periodicity in the individual. On the one hand the picture is that of an explosion of motor energy; on the other that of an explosion of sensory energy.

Each may be preceded by an aura referable to a disturbance in a definite cortical area. Although the aura of migraine presents the visual type in the form of scotoma and hemianopsia, while epilepsy commonly exhibits the pneumogastric aura, or the sensory or motor disturbance of the arm, face or leg; nevertheless, we may on the other hand have the migraine attack ushered in by paraesthesia of the arm, lip and tongue (with or without aphasia), while epilepsy may be preceded by visual disturbance, as dimness of vision or scotoma.

Not only may the same sort of an aura introduce an attack of epilepsy or migraine in different individuals, but in both diseases the warning may make its appearance independently without being followed by an attack. Just as in epilepsy the numbness of the hand or twitching of the fingers may come daily or several times a day over varying periods of time, only to be followed by the convulsive seizure at intervals of weeks, in the same way in a subject suffering from migraine attacks every few weeks preceded by scintillating scotoma, I have seen the appearance of daily attacks of the scotoma alone, over periods of weeks, each attack lasting from twenty to forty minutes.

The occurrence of psychic symptoms associated with the attack of migraine or epilepsy has been described by various authors; and indeed the attack in either disease may be replaced by a psychic equivalent.

Another common symptom frequently met with in both epilepsy and migraine is somnolence. It is astonishng to see a patient suffering intensely from hemicrania sleep soundly for a number of hours in the midst of the attack; and frequently attacks which come on during the day will disappear during sleep at night time. Just as somnolence appears often as part of the disease in migraine, so it may manifest itself in attacks of epilepsy, not as a result of exhaustion, but as a symptom of the disease. The following two cases are cited as illustrative of this rather than as being unusual in any way:

A boy of ten years, whose mother has suffered from periodical sick headaches since childhood, has had attacks for two years, in which there is a sensation of gas in the stomach lasting one or two seconds. When these come on he runs to his mother, saying he is afraid, and grasps her tightly, crying out "Don't let them hurt me!" or similar expressions. The pupils are dilated, the face congested and saliva drools from the mouth. The patient does not reply to questions, and after exhibiting these symptoms two or three minutes goes into a sound sleep for half an hour to an hour. Sometimes the pneumogastric aura is followed by convulsions.

A man of twenty-four years whose mother has periodical headaches lasting all day two or three times a year, has suffered for eight years from attacks of severe headaches, which always come in the left temple, recurring at intervals of eight or ten months. Each attack is ushered in by right hemianopsia, immediately followed by numbness of the right hand and wrist and right corner of the mouth, together with aphasia. This condition lasts half an hour, during which time the patient can walk around and understand conversation, but cannot speak. At the end of a half-hour dull headache in the left temple, associated with drowsy feeling and stupor appears, which, at the end of another half an hour, terminates with vomiting. If he can lie down and sleep when the aura begins, he awakes in less than an hour without discomfort.

The foregoing characteristics are only illustrative of points of *similarity* existing between the two diseases. There are however certain points of *relationship* which exist between them.

It is not the object of this paper to discuss the pathology of the two diseases in question. As is well known, various hypotheses have been advanced to account for the cause of the attacks in the two neuroses. None however can be accepted as generally true for all cases, and in comparing the two diseases we are forced to depend in accepting the diagnosis of migraine or epilepsy on the clinical picture presented. The features indicative of a relationship between epilepsy and migraine may be classed under the following heads;

(1) The interchange of one disease for the other in different generations of the same family.

(2) The appearance of migraine in early life, giving place to epilepsy later, with a resulting disappearance of the migraine or diminution of the intensity of the migraine attacks. In these

* Read at a meeting of the Boston Society of Psychiatry and Neurology, November 20, 1913.

cases the epileptic seizures may be ushered in by the same aura which gave warning of the earlier attacks of migraine.

(3) The development of migraine attacks in patients previously suffering from epilepsy, and in whom the epilepsy has been cured by bromide treatment.

(4) The appearance of symptoms of epilepsy in migraine attacks of certain individuals.

The interchange between epilepsy and migraine in different members or different generations of the same family has been remarked upon by various authors, as being significant in the consideration of the relationship of the two diseases.

Kovalevski found of the various hereditary diseases in the histories of patients suffering from migraine, that epilepsy occupies first place.

Bourneville found that migraine was present in the relatives of 24 per cent. of his cases of epilepsy.

Dejerine on analysis of Bourneville's cases found that in 250 epileptics 51.6 per cent. showed alcoholism, 24.5 per cent. migraine, and 21.2 per cent. showed epilepsy in the ancestors.

Féré, showed that in 108 cases of epilepsy, the father had migraine in 88 instances, and the mother had migraine in 116 instances. He further showed that out of 206 epileptic women, 40 had children who were affected with migraine.

Ulrich found that in five hundred cases of migraine 99 (or 20 per cent.) showed a direct or indirect relationship to epilepsy. In about 8 per cent. there was epilepsy in the relatives of the patients; in about 12 per cent. migraine and epilepsy occurred in the same individual.

The fact that attacks of epilepsy and migraine sometimes alternate with more or less regularity in the same person, may be due to the coincidence that the patient is suffering from the two diseases. For it would not be strange that two diseases so commonly found thriving on neuropathic soil should at times afflict the same individual. But substitution of one disease for the other in a person, or the occurrence of symptoms common to both diseases in an attack must indicate relationship. The occurrence of migraine in the early years of life of individuals giving place to epilepsy in the later years was first described by Liveing in 1873.

He cites the case of a woman of thirty-seven years, suffering from epileptic fits. The patient's brother and sister were both epileptic, though there was no history of the disease in either parent. The patient suffered from the age of twelve with sick headaches, coming chiefly at the menstrual period. These were frequently preceded by a visual aura of dim vision and numbness of the fingers. At the age of thirty-five the headaches stopped and were replaced by epileptic seizures, which also came at the time of the catamenia.

Liveing quotes another similar case, and follows it by a number of instances showing the connection between these two diseases, collected from the literature of the times.

Krafft-Ebing reports a case in which the epileptic attack ends in a hemicrania.

A woman of twenty-six years, whose mother and sister had suffered from hemicrania, had been subject since puberty to attacks of premenstrual migraine with scintillating scotoma. Two years previous to the time he first saw her, she had been observed to manifest a lapse of consciousness, which lasted about ten minutes, that is, as long as the scotoma had continued, during which time she made inarticulate noises and did not respond to questions. At the end of ten minutes, the patient regained consciousness, suffering from hemicrania, but was amnesic to all events which transpired during the disturbance of consciousness. Five months later she had her first epileptic attack during sleep, and when the convulsions had ceased she came to herself with her usual headache. Since that time the epileptic attacks have come always at night and are always followed by hemicrania.

Spiller reports two cases of patients who had had migraine since early life, in whom symptoms of abortive forms of epilepsy made their appearance later.

Gowers reports the case of a woman aged thirty-two years, who, at the age of eight years became subject to periodical headaches, which were preceded by dimness of sight, and usually ended after some hours with vomiting. They continued until the age of thirty years, when she became subject to epileptic fits. The headaches ceased entirely when the epilepsy began, and remained absent until she came under treatment. While under treatment the fits were arrested, but the headaches returned with greater severity than ever.

Turner cites the case of a man of thirty-six years, whose father was a confirmed epileptic and whose sister suffered from paroxysmal headaches. The patient had epileptic fits from the age of sixteen to twenty-five years, when they ceased and gave place to attacks of paroxysmal headaches, coming on in the early morning, lasting about three hours, and recurring every week or ten days.

Flateau in his recent monograph on migraine reports the case of a woman thirty-four years old, whose mother and sister had suffered from migraine, and who at the age of 17 had severe attacks of headache lasting two days. When menstruation began the headache attacks increased in severity. During the last three years before Flateau saw her she had developed typical epilepsy, and the headaches had ceased.

The following case was recently seen by the writer at the Massachusetts General Hospital.

She was a woman of twenty-seven who had been subject to periodical headaches from early childhood up to the age of nineteen. These headaches were preceded by blurring of vision, and were associated with vomiting. Her great grandmother suffered from paroxysmal headaches, but otherwise her family presented no history of epilepsy or migraine.

At the age of nineteen the attacks of headache ceased and were replaced by dream-like periods lasting several minutes, during which the patient was unable to move and could not reply to questions. In these periods the patient says there is a train of thought that she cannot afterwards recall. During the past year these attacks have given place to typical epileptic convulsions, recurring every two weeks in which the patient usually hurts herself in the fall, and has bitten her tongue. By the advice of her doctor she was recently married in the hope of thereby curing the attacks.

Hemianopsia as an aura in epilepsy is of rare occurrence. Gowers maintains that it never occurs, but as is well known, it is frequently seen as the first stage in an attack of ophthalmic migraine. The following case observed by the writer illustrates the fact that it may occur as an aura of epilepsy, and so closely does it conform to the migraine type of hemianopsia in its character and long duration before the attacks that it strongly suggests a relationship between the two diseases.

A man of thirty-four has had attacks of epilepsy since the age of eighteen. There is no history of epilepsy in his parents or in their immediate relatives, except that his mother's father who was alcoholic had convulsions in late life. The patient has one brother and three sisters, one of whom has severe headaches periodically, which are not, however, associated with eye symptoms.

The patient has had convulsive attacks since the age of eighteen, coming four or five times a year. These are always preceded by a right hemianopsia. The loss of vision begins on the right side and extends inward until it reaches the median line in the course of one or two minutes, and at the same time there may be flashes over the blind field after the hemianopsia is well established. The hemianopsia lasts from fifteen to thirty minutes before unconsciousness sets in. This delay usually enables the man to reach home from his office before the convulsions begin. The loss of consciousness is immediately followed by general convulsions, lasting several minutes, after which he lies in a heavy sleep two or three hours, and awakens with a heavy feeling head and is lame all over for from one to three days. The attacks persist with the same frequency in spite of liberal doses of bromide and careful regulation of the general condition.

From the age of ten to eighteen years this patient had severe headaches two or three times a month which came on during the day or night and lasted three to five hours. The pain was across the forehead, never limited to one side of the head, and was never preceded by scotoma or hemianopsia, nor followed by vomiting.

Krafft-Ebing, Savage, Féré, and Cornu have shown that in certain cases where epilepsy attacks have been cured by the bromide treatment, migraine may develop as a substitute, and Flateau asserts that his experience corroborates this.

The following case, a patient who has been under the observation of the writer for five years, will illustrate this point.

He was a boy of 14 years when first seen in May, 1908. There is no history of epilepsy or migraine in either parent or in their families. At the age of two, while teething, he had a convulsion lasting five minutes. At the age of three, while feverish with bronchitis, he had a second convulsion lasting five minutes. A third convulsion was at the age of six, and the fourth at the age of eleven. For the three years previous to the time he was seen by me, he had had convulsions every three to six months, mostly in the morning before getting up. The attacks were of a typical form of major epilepsy. He had led his class at school in studies, and excelled in athletics. Under treatment of regulation of diet and moderate doses of bromide the attacks ceased. Three years later however, while still under treatment, he had an attack which he described as follows:

"On the 28th of April at eleven a. m. I was suddenly seized with a dimness of vision which lasted twenty minutes, at the end of this time I could see as well as ever, but the instant the dimness left I felt a drawing sensation at the tip end of the thumb of my left hand for a space of two minutes. This sensation passed from one finger to the other in the order of the fingers and up into the hand, the little finger receiving the strongest drawing. I then felt the same sensation half way up the left arm and in the upper lip and roof of the mouth on the left side of the face, all of which passed away in two or three minutes, and was followed by dull headaches over the eyes."

During the next two years these attacks were repeated at intervals of three to six months, and not until recently did the convulsions return, when the patient became lax in following his treatment.

That the headache attack with its visual and paraesthetic aura which replaced the convulsion, was not an abortive form of epilepsy seems probable, since it presents the clinical picture of migraine. As is well known, the aura of migraine lasts over a prolonged period of time, while that of epilepsy precedes the attack by only a short interval.

This case is interesting in connection with one reported by Féré in his book on "Les Épilepsies et les Épileptiques," written in 1890.

A woman of fifty-four years while writing a letter suddenly felt a severe pain over the right eye, and "the flickering lights of a thousand candles" appeared on the right side of her field of vision. So severe and sudden was the pain that she thought some one had thrown a stone at her, and on going to the door to see who had done it, met her husband, and was surprised to find she could not see the left half of his face. When she tried to explain to him her condition, she was unable to manage her tongue, or to articulate her words. She then felt her fingers and thumb of the left side flex on the palm with a pain extending up the forearm, and the whole arm was raised to the height of the shoulder, while the face was turned toward the right and the lips were seized with convulsive twitchings. These convulsive movements lasted only a minute, but the headache, hemianopsia and aphasia persisted for fifteen minutes. At later intervals there were five recurrences of similar attacks, and when bromide treatment was instituted the convulsive attacks no

longer appeared; only the pain, scintillating scotoma, and hemianopsia remained.

The occurrence of migraine attacks and epileptic seizures in the same individual and ushered in by the same visual aura has been described by various authors. The following case, observed by the writer, is an excellent illustration of this phenomenon:

A man thirty-seven years old, a tanner by trade, gave a history of migraine in both parents: the mother had periodic sick headaches as a girl, but outgrew them in middle life; the father has had periodic occipital headaches of great severity, associated with vomiting, ever since he can remember. There was no history of epilepsy in the family.

The patient had periodic headaches with nausea and vomiting as a boy, which continued until he was eighteen, none of them being associated with visual disturbance.

About three years previous to the time he was seen by the writer, he began to have left supra-orbital headaches, preceded by flickering scotoma, but not associated with nausea or vomiting. He had forty or fifty of these attacks during the three years, always coming on in the day-time and lasting a number of hours. His scotoma consisted of a luminous spot before the eyes, which contracted and expanded like the opening and closing of a butterfly's wings.

About two years previous to his first visit, he one day had a violent attack of the scotoma, and lay down on a couch, asking a companion to get him a glass of water from the next room. The last thing he remembered was that the furniture in the room appeared to be jumping up and down with the flickering of his scotoma. When his companion returned with the water the patient was found on the floor in a general convulsion.

Two similar attacks occurred later at intervals of about six months—one in a barber's chair, the other while driving.

The writer was called in consultation to see this patient, who was suspected to be suffering from a brain tumor. Three days previously he had been found in bed in the morning suffering from intense frontal headache. This had persisted since and had required hypodermic injections of morphine. There had been occasional attacks of vomiting during this time. The patient had been much run down during the previous months with overwork and domestic worries.

The physical examination showed a well-developed man. The pupils were equal and reacted well. Ophthalmoscopic examination was negative. There was no impairment of any of the cranial nerves. The reflexes were normal. There was no Babinski. The temperature was 98.6, the pulse 45, and blood pressure 130.

For many days preceding the onset of this severe and prolonged headache, and for several weeks following it, there were daily attacks of the flickering scotoma lasting a few seconds, sometimes occurring two or three times a day; and a subsequent examination of the visual fields by Dr. George Derby revealed a homonymous scotoma still persisting.

The persistence of a scotoma of this sort would raise the question as to the existence of a permanent organic lesion of the brain, which might account for the appearance of the convulsive attacks. Cases have been described however, in which the scotoma may continue for a long time after the attacks of ophthalmic migraine. Inasmuch as we often find patients suffering from ophthalmic migraine exhibiting at one time the scotoma followed by the headache, and at another time accompanied by a headache, just as the aura which precedes epilepsy may be followed by the convulsion or occur independently, it is difficult to say whether the above patient's minor attacks should be considered as attacks of aborted epilepsy or migrainous scotoma.

The appearance of symptoms of epilepsy and migraine in the same attack of an individual has been noted by various observers.

Tissot in 1780 wrote that he had very often seen convulsive movements of the forehead, eyelids and face muscles, associated with migraine, and that sometimes the convulsions involved the entire body.

He described the case of a girl of twelve, who together with the hemicrania attack felt a numbness in the little finger of the same side, which spread successively to the other fingers, the forearm, upper arm and neck with occasionally a spasmodic retraction of the head and spasm of the jaws. There was no loss of consciousness, but the attack was followed by vomiting.

Parry in 1825, wrote that he had seen instances of obfuscation of sight lasting many hours after an epileptic fit, from which the patient was otherwise fully recovered. In his case it was only the perpendicular half of the object that could be seen.

Price reports the case of a patient, twenty-one years old, whose father suffered from attacks of severe headache, preceded by blindness for a few seconds, and then by numbness of the arms, tongue and lips. The father also had two sisters afflicted with migraine. Six out of seven of the patient's brothers and sisters also had migrainous attacks, and in three of them the headaches were associated with numbness or weakness of one half of the body. The patient had had paroxysmal headaches since he was six years old, coming several times a year and occasionally preceded by numbness of the right side of the body. This paresthesia began in the toes and crept up, affecting in succession the leg, arm, trunk, face and tongue, being felt most markedly in the hand and foot and but slightly over half the trunk. At times he had been unable to control the affected arm and leg during the attack. The paresthesia lasted from twenty minutes to an hour, and was followed by severe hemicrania on the side of the head opposite the numbness, lasting from twelve hours to three days. Other attacks were preceded by blurring of vision and hemianopsia. In a "light attack" seen by Price, the face was pale, the lips cyanotic and the speech thick; while occasional twitchings of all four extremities were noted, the arms flexing at the elbows, and the thighs adducting.

That epilepsy is related to migraine is still denied by certain men who have written on the subject, although the majority of the authorities accept the fact.

Liveing in his early work on migraine published in 1873, recognized the relationship between epilepsy and migraine. He writes, "Epilepsy is doubtless the neurosis which exhibits the closest connection with megrim, both in the occasional replacement of the one affection by the other, and also in the occurrence of cases of character intermediate between the two."

Féré says that epilepsy is among the frequent accompaniments of ophthalmic migraine, especially partial epilepsy. Ophthalmic migraine may develop in a person who has previously had partial epilepsy and still has attacks of paraesthesia in the side of the body in which the epileptic movements occurred. He also speaks of cases in which migraine may precede epilepsy, or the two may occur together, or in which the migraine may become less severe after the epilepsy has made its appearance.

Wernicke in 1881, maintained that migraine is not infrequently complicated with certain phenomena of epilepsy, and may appear as a forerunner of epileptic attacks.

Kovalevski calls attention to the substitution of one neurosis for the other. Epstein regards migraine as the equivalent of epilepsy in some cases. Cornu maintains that one neurosis may be transformed into the other. Charcot and Krafft-Ebing maintain that when scintillating scotoma appears in an epileptic attack it is related to migraine. Oppenheim writes that migraine sometimes, though rarely, develops into epilepsy.

Turner, in his book on epilepsy, states that he has observed a relationship between epilepsy and migraine in 4.3 per cent. of his cases. This relationship manifested itself in one of the four following ways:

(a) Periodic headaches in one parent, and epilepsy in the off-spring, and vice versa.

(b) Headaches in early life, replaced by epilepsy in later life.

(c) Epilepsy in early life, replaced by headaches in later life.

(d) Both existing simultaneously in the same individual.

Spratling, in his book on epilepsy, gives but little space to its relationship with migraine. In speaking of the sensory equivalents of epilepsy, he writes "The Migraines also belong to this group. The relationship between these affections and epilepsy has long been in dispute. I believe it is associated with the disease, especially in women, who more frequently show a periodicity in convulsive phenomena than men."

Ulrich recognizes the following conditions to explain the occurrence of epilepsy and migraine in the same patient:

(1) Migraine may exist as a symptom of epilepsy.

(2) Both may develop side by side in an individual, springing from the same low order of nervous development.

(3) Severe migraine attacks may produce convulsions.

(4) Constant recurrence of migraine attacks may lead to the development of true epilepsy.

(5) Migraine attacks may disappear as epilepsy develops, just as they do in the development of grave organic diseases of the brain (dementia paralytica).

Spiller expresses his views on the subject by the following remarks:

1. Attacks of migraine occur with nausea and vomiting; this form is known as simple migraine, and usually remains unaltered during the life of the patient.

2. In other cases visual disturbances (hemianopsia, scintillating scotoma, and amaurosis) are associated with migraines, and the disease is known as ophthalmic migraine.

3. When paralysis of the ocular muscles occurs with the migraine, the disease is described as ophthalmic migraine.

4. Migraine, especially the ophthalmic form, is related to epilepsy, and the attacks of migraine may precede for many years the convulsive attacks of epilepsy, although in most cases of migraine, no convulsions are ever detected.

5. In some cases epilepsy appears in the form of one or more of the disturbances seen occasionally with migraine; and later, even after many years, convulsions develop. The disease may be epilepsy from the beginning. It matters little, with our uncertain knowledge of the pathology of the two diseases whether we regard these as abortive cases of migraine that later become associated with epilepsy, or as abortive forms of epilepsy (sensory epilepsy) in which the convulsions later become apparent, provided we recognize a relation between some forms of migraine and epilepsy.

Flateau in a study of five hundred cases of migraine has observed a relationship to epilepsy in thirty-six cases, or 7.2 per cent. In certain of these cases the attack in the individual manifested itself first as migraine, then as epilepsy of the petit mal type, and finally in later life as convulsive attacks with the epileptic Dämmerzustände.

Among those denying the existence of a relationship between the two neuroses in question the opinions of the following men are to be valued in the light of their wide experience with these diseases:

Gowers writes, "The traces of a definite relation of migraine to epilepsy are slight. In extremely rare instances one affection may develop while the other goes an, and, as we have seen, the same premonitory disturbance may even be at-

tached to each. But such cases are so rare as rather to emphasize the rule to which they form exceptions. When the exceptions are carefully examined, they show that any relation to epilepsy is indirect. Epilepsy develops from migraine as an indirect consequence of the effect of the intense pain, and associated cerebral disturbance. The influence of this may be traced through stupor, sleep, delirium and loss of consciousness, to definite epileptic symptoms."

Hubbell, the ophthalmologist, states that he has questioned three to four hundred patients who were afflicted with ophthalmic migraine, and in not one of them has he found that epilepsy existed in any form, nor was epilepsy described in the antecedents or descendants of the patients.

Strohmayer has often found epilepsy and migraine existing in the same person, the epilepsy usually making its appearance later than the migraine. Substitution of one for the other he has not found. When this appeared to take place the migraine was but a symptom of the epileptic condition, or epilepsy made its appearance as a new element in addition to the migraine. In the atypical cases, the diagnosis between the two diseases may be difficult.

Moebius maintains that migraine is essentially different from epilepsy. Under certain circumstances it may be impossible to say whether migraine or epilepsy exists, as when the aura alone appears. But in such cases it is either one or the other. The difficulty lies only in the inability to recognize which it is. If we put aside the rare cases in which migraine turns into epilepsy, we have only to consider the cases in which epileptic as well as hemieranic symptoms exist. In these cases we are concerned with epilepsy which simulates migraine. As a general rule we can assume that where there are convulsions the case is one of epilepsy. "Migraine symptoms," he says, "are exclusively sensory and I never made a diagnosis of migraine where there is the slightest appearance of convulsions at the corner of the mouth or in the tongue. One can say, that when convulsions appear in an attack it may seem to be migraine but is in reality abortive epilepsy."

Moebius denies for instance that the case of Féré cited above represents a change from epilepsy to migraine, but maintains that it indicates that through bromide treatment the convulsive feature of the attack has been eliminated, leaving what is really an abortive form of epilepsy.

That the attacks similar to that reported by Price, and described in the foregoing pages of this paper, should be relegated to the province of epilepsy according to the claims of Moebius, on account of the twitching spasms of the limbs, seems arbitrary, inasmuch as the clinical picture is that of migraine; for we must admit that paraesthesia of long duration is an aura distinctly characteristic of migraine, as is also hemianopsia, while the absence of loss of consciousness with the prolonged hemicrania, complete the clinical picture.

One cannot review the statistics of various authors which describe the frequent interchange of epilepsy and migraine in different generations of the same family without being convinced that they indicate a definite relation between the two diseases. Nor can one read the histories of the cases described in the earlier pages of this paper in which substitution of one neurosis for the other occurs in the lifetime of the individual without having his conviction of this relationship strengthened.

Moebius in denying that there is a relationship between the two neuroses puts this evidence aside with the statement, "If we regard the rare cases in which migraine turns into epilepsy," while Gowers passes by the importance of this relationship with the statement "If a person subject to migraine becomes liable to epilepsy, the migraine may cease, or become slight or rare, and return if the fits are arrested."

We must also accept in considering the relationship the group of cases in which bromide treatment of epileptic fits changes the clinical picture of the attack from that of epilepsy to that of migraine.

We still are confronted however, with those cases presenting attacks apparently migranoid in character but also associated with convulsive movements. Shall we accept the dictum of Moebius that the presence of convulsive movements must relegate these cases to the domain of epilepsy? It seems to me that since we must accept a relationship between the two neuroses in different generations of the same family and in different attacks of the same person, that surely we may recognize that symptoms of epilepsy in an attack of migraine may indicate the existence of a relationship between the two diseases in that attack, and need not, according to the dictum of Moebius, stamp that attack as essentially epileptic.

A RADIOGRAPHIC STUDY OF THE MASTOID.

BY OLIVER A. LOTHROP, M.D., BOSTON,

Assistant Otologist, Massachusetts General Hospital; Clinical Assistant, Massachusetts Charitable Eye and Ear Infirmray.

THE following observations were made from a large series of X-ray plates in possession of the Massachusetts Charitable Eye and Ear Infirmary and I wish to thank the various members of the staff for their permission and assistance. In many instances the X-ray interpretations could be verified by operative findings.

The use of the X-ray plate for aid in diagnosis of mastoid conditions is recent and promises to be of great value, especially in differential diagnosis between an acute mastoiditis and an acute exacerbation of a chronic sclerosed mastoid. As a rule, the mastoid picture shows a more minute change in pathology than is shown in that of the accessory nasal sinuses. The reverse is true perhaps of transillumination. For detecting changes in the antrum of Highmore, for example, the transilluminator is more accurate than the X-ray, but in the mastoid the X-ray will differentiate between a congested though cellular mastoid, one whose cells are broken down and one that is sclerosed, while the transillumination of the mastoid simply shows some pathological condition obstructing to different degrees the rays of light.

It is not necessary to go into the details of how the X-ray exposures are made and the plates developed. Suffice it to say that the side of the head to be skiagraphed is laid on the photographic plate with the film side up. Sometimes the auricle is left in its natural position and at other times it is turned forward. The rays are directed through the head from a point posterior to the opposite mastoid, so as to avoid superimposing any dense structures of the head. For this reason the bony external auditory canal is not shown as a distinct oval but more as a mottled area, and other relations are more or less distorted. The more carefully a plate is exposed and developed, the more accurate and easy will be the interpretation. A sclerosed or normal cellular mastoid can be made out in almost the poorest plate but for interpretation of slight pathological changes in acute matoiditis a good plate is an absolute necessity. Plates of both mastoids should be taken in all cases for comparison.

The normal cellular mastoid projection shows the cellular spaces clearly and the thin partitions are clear cut. Anterior to the cellular area is a roughly triangular, dense area which is the petrous portion of the temporal bone. Within this area the bony meatus shows as a less dense and mottled spot. Had the projection been taken in the direction of the auditory canal, the meatus would have been shown as a hole. Anterior to this triangular area is seen the ascending ramus of the jaw and its articulation. The upper border of the triangular area is formed by the zygoma and its projection posteriorly as the linea temporalis. The middle cranial fossa lies above the border. The zygomatic cells, when present, often show projected in and above this border. The antrum in a normal, cellular mastoid is rarely distinguishable from the other cellular spaces. The position of the lateral sinus and sigmoid curve can generally be made out but is not as distinct as in a sclerosed mastoid. As in the latter, the anterior border is more distinct. In a general way, it passes from the upper, posterior part obliquely downward and forward to the bulb which lies under the middle ear. The tip is always seen as a distinct free border. The tip may be more or less solid or filled with cells so as to leave only a shell-like cortex.

Posterior to the sinus is seen the posterior cranial fossa in which lies the cerebellum. The suture lines of the occipital, parietal and mastoid bones often can be seen distinctly. In the young the cellular area is much restricted and the cells are generally smaller than in older individuals. Not unfrequently there is much variation in the size, shape and arrangement of cells in different cases but there is a striking similarity between the two mastoids of the same individual. If there is a small mastoid on one side, the other will be small. If one mastoid has small diploëtic cells, the other has also, or if one has large pneumatic cells, such are found in the other. The outline of the cellular area is generally similar in both. The auricle must be mentioned here, not because we desire its projection, but because its shadow frequently masks or accentuates some border and allowance must be made for it.

The X-ray picture of the mastoid in acute conditions varies as the pathological processes advance. In the majority of cases of acute otitis media the mastoid cells are affected simultaneously, even though the pathological condition be only a participating congestion. In all severe infections the mastoid cells are probably likewise infected, and pus from the mastoid is added to that from the middle ear. In this congestive stage the natural cellular appearance of the mastoid would be preserved with the exception that there would be a loss of definition between the cell spaces and their partitions. In fact the whole plate of the mastoid region shows less penetration to light than the other side. This is the most difficult stage of mastoid inflammation to interpret. Almost perfect plates of both sides, equally exposed and developed, are required. This picture can be simulated by other inflammations and congestions of the surrounding soft parts, most commonly, furunculosis of the external auditory canal. Fortunately, this

stage of mastoid involvement rarely requires surgical intervention.

After six to ten days the picture changes in cases of virulent mastoiditis. There is now seen a distinct blurring of the mastoid structure. The cell partitions are barely made out and there is very little contrast between the cell spaces and their partitions. At the end of this time, actual loss of some cell partitions may be made out. In such a mastoid, the cell spaces would be found filled with pus, the mucous membrane lining swollen and polypoid, and there would be some softening of the bony partitions.

Plates of mastoiditis which has progressed for two, three or four weeks show still different pictures and usually are easy to interpret. At this stage is noted distinctly loss of cell partitions, especially in the tip or in the center over the lateral sinus. Areas less affected by the pathological changes still show blurred cellular structure. Later, well advanced cases may show no cellular structure in any part and may even show cavity formation due to destruction of bone. These mastoids, as found at operation, are very vascular, broken down, and filled with granulations and a little pus.

Perisinous abscess in the central portion of the mastoid is sometimes diagnosed in those cases above spoken of where cavity formation is noticed is that region. Where the bony wall of the sinus and the cellular structure over it has been absorbed by the pathological process, it is conceivable that such a cavity should show in the plate because the rays can thus more easily penetrate that area. A perisinous abscess well posterior, and an extradural abscess, both being partially beyond the limits of the normal cellular mastoid, frequently show up distinctly. The impression is that of a cavity or less dense area surrounded by a dense areola fading off gradually above and posteriorly. A brain abscess has not been observed. Sinus thrombosis is probably not recognizable to any extent. There is no reason to believe that clotted blood has any different effect on the penetration of the rays than fluid blood. The reason for the impression of the lateral sinus on the plate will be spoken of in connection with the sclerosed mastoid.

There are many cases of mastoiditis that never come to operation and, after weeks or months, the majority get well. The X-ray seems to throw some light on what happens to the mastoid in these cases and how nature cures them. It has been mentioned that the cell partitions are absorbed as the process goes on and all the spaces are filled with granulations and the quantity of pus is diminished as the virulence of the infection is gradually overcome. Have we not now a condition similar to that after operation when the mastoid cavity has been cleaned out and later filled with granulations in the process of healing? What happens to the post-operative cavity? Regenerated bone, usually homogeneous, but rarely cellular, fills the cavity as is seen in X-ray plates of old post-operative cases and as is found in operating on cases of recurrent mastoiditis. In the post-operative cases the bone regenerates from the periphery of the cavity and frequently leaves a seam of fibrous tissue directly under the cicatrix of the incision. It is also observed that bone is not regenerated in the area where the sinus was uncovered by operation. With the above clinical and X-ray evidence that post-operative mastoid cavities fill in with granulations followed by regenerated bone, can it be doubted that this same process takes place in an unoperated case cured by nature? A few of these transition cases were found in which the X-ray showed almost a homogeneous shadow and at operation a soft, bleeding, regenerating bone and granulation tissue was found but no pus. If for any reason, as, for example, carious ossicles on a marginal perforation, the antrum and middle ear did not heal as the mastoid was filling in with bone, a chronic suppurative ear would result.

We have considered above what takes place in an adult, fully developed mastoid. Let us now consider what would be the result in babies and young children where there is only an antrum and rarely a few cells budding off. In this group occur a goodly proportion of our acute suppurating ears and it is a well known fact that discharge from a baby's ear is very chronic. When operation is performed the antrum is found filled with granulations. Though the antrum is of about adult size, the mastoid tip and surrounding parts are proportionally smaller and close to one another. The normal antral lining has been destroyed so that as the child grows the budding off of cells will not take place. The bony parts will enlarge some but not in proportion to those filling with cells. The sinus is left nearer the antrum and the groove is deeped in the bony parts. Does not this explain the small, sclerosed mastoid of later life with its ivory like texture and its lateral sinus so close to the posterior wall that easy access to the antrum is impossible? On the other hand, how rarely does a lateral sinus obstruct the surgeon's passage to the antrum in an acute cellular mastoid.

Let us now consider the appearance of the sclerosed mastoid in the X-ray plate. The sclerosed mastoid is the type always seen in cases that have or have had a chronic suppurative middle ear and mastoid. So constant is this relation that with one exception, all cases diagnosed clinically as a chronic suppurative ear showed a sclerosed mastoid. The one exception was a case of atresia of the canal with granulations and foul pus. The mastoid was cellular and the middle ear normal after curing the canal. The reverse, however, is not so constant. Acute exacerbations of a chronic suppurative ear or acute otitis media in an ear which was once a chronic suppurative ear frequently can-

not be differentiated clinically from an acute attack in an otherwise normal ear. Here, the X-ray shows us the past history as represented by a sclerosed mastoid. And again, given an X-ray plate of a sclerosed mastoid, it is practically impossible to detect the presence of an acute inflammation.
